**HONORED LIFE MEMBER
BRIAN L. BAYNE**

Take a passion for marine science, a piercing intellect, and a zest for life, and mix them all together under the heat of a Caribbean sun, and it's a heady brew! No question either about the talent for marine biology and molluscan physiology—any guy who kicks off his career with a single-author paper in *Nature* means business!

Brian, one of four brothers and a fourth-generation Trinidadian, was born in the West Indies in 1938. He grew up in and on the water, his favorite activity being scuba and spear fishing, in which his Dad was a pioneer. His love of the sea and interest in marine animals thus developed from an early age. He was sent to boarding school in Barbados at the tender age of 8. He matured rapidly when at 15 he persuaded his parents to send him to Ardingly College in the U.K. to complete his high school education. His boarding school years were successful academically, producing exam successes in chemistry, zoology, and botany, but less successful socially, producing a definite absence of the famed English reserve and stiff upper lip. Following a year in the "smoke" at Queen Mary College, University of London, he negotiated a transfer to University College North Wales, Bangor, to be closer to the sea. He graduated with a First in 1960 and promptly celebrated by marrying a softly spoken Welsh beauty, Marianne. He then took the long walk over the bridge from Bangor to Menai Bridge to obtain a Ph.D. in double quick time in 1963 under the benign aegis of Professor Dennis Crisp, working on the reproduction and larval ecology of mussel larvae.

Desirous of working with the best and expanding his scientific horizons, Brian and Marianne packed their bags and took off for the various corners of the world. Two years in Helsingor, Denmark, as a Churchill Foundation postdoctoral fellow working under Gunnar Thorson (University of Copenhagen) on the growth and metamorphosis of bivalve larvae, was followed by one year as a Visiting Research Fellow at the University of Sao Paulo, Brazil. Here Brian was introduced to respiratory physiology by Kjell Johansen (University of Washington, U.S.A.), so sparking off a life-long interest in the comparative physiology (functional biology) of bivalves.

Eventually, the lure of the tropics was overcome, presumably by the beer and "singing in the hills" of Wales, as Brian returned to spend two years as a Senior Research Fellow at the Shellfish Research Laboratory, Conway, working on the settlement and gregarious behavior of oyster larvae. This was followed by six years as a lecturer in the newly formed School of Biology at Leicester University, where residence in England's heartland was overcome by the construction of excellent recirculating seawater facilities and the choice of the hardy mussel *Mytilus edulis* as the experimental animal. During this period, a "tropical fix" was obtained via a Nuffield Research Fellowship, working six months at the University of Kuala Lumpur, Malaysia, and six months at Phuket Biologic Laboratory, Thailand, on the physiology of mangrove bivalves. In these early years, scientific productivity was matched by reproductive productivity, with the birth of daughters Julia in 1964 and Siân in 1968.

In 1973, Brian moved to Plymouth as a Principal Scientific Officer at the new Institute for Marine Environmental Research (IMER), working on the functional physiology and ecology of mussels. Stardom and relative fortune rapidly followed as Brian ascended the scientific and managerial ladder of fame. Promotion to Senior Principal Scientific Officer was followed by appointments to Director of IMER (1983), Director of the Plymouth Marine Laboratory (PML) (1988: formed from IMER and part of the Marine Biologic Association, U.K.), and finally in 1994, the dizzy heights of Director of the Center for Coastal and Marine Sciences (CCMS, comprising PML, Proudman Oceanographic Laboratory, and Scottish Association of Marine Sciences). Directorial qualities were tested to the full in orchestrating the delicate creation of PML and navigating the choppy waters of the genesis and functioning of CCMS. But enough was enough of managerial time consuming research time, and in 1997 Brian swapped the desk for the bench and became Research Professor and Deputy Director at the Center for Research on the Ecological Impacts of Coastal Cities, University of Sydney, Australia. He held this position until 2000, using oysters to extend work on the role of genetic variation on feeding and growth of bivalves, in the field of evolutionary physiology.

Science has been the major driving force in Brian's career, and his contribution to bivalve physiology, ecotoxicology, and adaptive biology is immense. His talents at the bench were manifest from the beginning in the rearing, handling, and experimentation of larval to adult animals. He sensed early on that bivalves were far more complex and interesting in their functional biology than was commonly appreciated, and that by applying relatively simple physiologic principles, it was possible to understand functional attributes. He was intrigued as to how such attributes could be used to analyze environmental quality, as well as understanding the adaptive features of the animals themselves. As different genetic stocks became available, so he researched the balance between environmental and genetic factors in determining phenotypic traits, leading to his current interest in the evolution of life histories.

He led substantial research groups from Leicester onwards, siring sixteen Ph.D. students, including a number of talented physiologists and the "odd" biochemist. Attracting a wide multidisciplinary team, the *scope for growth* and related approaches were developed, the legacy of which is that biologic effects measurements in mussels are today used worldwide in pollution monitoring. In later years, his bivalve research focused on the molecular bases underlying the physiologic advantages of genetic polymorphism, slower protein turnover being shown to explain faster growth. Studies on the interrelations between seston and bivalve feeding have helped define conditions for sustainable environmental shellfish aquaculture. Throughout his research career, Brian has benefited from and enjoyed collaborations with students, post-doctoral fellows, and fellow scientists, both at home and around the world. He has published some 180 primary papers, reviews and book chapters, and research funding has been obtained from many national and international grants.

Under Brian's directorship, IMER and PML continued to flourish into a major force in marine biology, attracting a host of talented staff and international visitors. In addition to the usual directorial qualities, this was achieved by Brian's own research pre-eminence and enthusiasm, plus a multidisciplinary breadth of knowledge that gave every scientist a fair shout and throw of the dice. Whatever the climate, fundamental studies were always encouraged. Inevitably, time for hands-on research was reduced, but ties were maintained by Visiting Research Fellowships to the State University of New York and Universities of Cape Town, South Carolina, and California at Davis. When schedules permitted, Brian would also be found back in the physiology laboratory, crouched over equipment, with concentrated disposition and faithful tea towel over the shoulder. And the first was always there! When a younger colleague quipped that it was good to see an old pro back at the bench, it was intimated where a scientific leg with scientific foot and boot attached might be heading if such flippancy persisted! And the same fire was taken to cricket matches with rival laboratories where no quarter was asked and none was given! In one infamous game, a foreign visitor, ignorant of the rules, was kept in conversation way outside his line of safety, while Brian snook up and dismissed him by whipping off his bails (for the non-cricketers amongst us, the aforementioned items refer to small horizontal wooden structures and not to a part of the man's anatomy)!

Such a distinguished career inevitably brings honors and accolades, and Brian has collected more gongs than you would find on a field marshal's chest. These include Honored Life Member Award of the National Shellfisheries Association, for which he is particularly pleased; Professorial Fellowships at the U.K. Universities of Plymouth, Sheffield, and Wales at Swansea; Honorary Fellowship at his *alma mater* University of Wales at Bangor; and Fellow of The Institute of Biology, the Zoological Society of London, The Royal Society of Arts, and The European Environmental Research Organization. Not surprisingly, word eventually reached the palace, and in 1998 he was awarded the Order of the British Empire for services to marine science. He has served on some thirty national and international committees, and seven international journals, including managing editor of the *Journal of Experimental Marine Biology and Ecology*.

Brian is an avid and accomplished single-handed sailor, and has spent much of his later years exploring the English Channel and further afield to Ireland, Scotland, and the Atlantic coasts of Spain. Avoiding the offshore passages, Marianne sensibly likes to join Brian once the boat has arrived at a pleasant cruising destination. I, along with other students, owe Brian much for being shown the correct way to do research, with thoroughness, no compromise, and integrity. I remember fondly the laugh to shake and warm your socks, the decisiveness (when it was time to go, it was time to go!), and the perceptive reasoning that cut straight to the heart of a debate amid the whirring of a cacophony of disparate arguments. Brian continues to work on the Australian study and to sail into various scientific and nautical ports. I can see him now, standing on the poop deck, gazing at the horizon, a broad smile alternating with a furrowed brow and intent peer that would send any perfect storm scuttlin' for cover! Sail on science boy, and congratulations on a career well done!

Dave R. Livingstone

HONORED LIFE MEMBER JOHN HOOD RYTHER

John Hood Ryther was born in Newton, Massachusetts, in 1922. He attended Newton High School before joining the U.S. Army Air Force. He served from 1941 through 1945 and rose to the rank of Captain and Pilot. He subsequently attended Harvard University, receiving the degrees of A.B. (Cum Laude) in 1947, M.A. in 1950, and Ph.D. in 1951. John joined the staff of the Woods Hole Oceanographic Institution in 1951 as Research Associate. This was the beginning of a lifelong relationship during which he rose to the rank of Senior Scientist and served as Chair of the Biology Department and Director of the Coastal Research Center. John currently enjoys the status of Scientist Emeritus at Woods Hole. His prolific research career included many original and landmark contributions on primary productivity in the world's oceans, and in later years, numerous aspects of aquaculture. As his research in aquaculture grew John found an interested friend in the late Seward Johnson, and in 1983 John assumed the Director position of the Division of Applied Biology at the Harbor Branch Institution, Fort Pierce, Florida. He remained in that position until his retirement in 1987. John now resides with his wife Jean in North Falmouth, Massachusetts, where he enjoys his children, his growing grandchildren, and every opportunity to go fishing.

John's expertise and guidance were widely sought throughout his career. John served as a corporation member of both the Marine Biologic Laboratory at Woods Hole (1955–1981) and the Bermuda Biologic Station (1955–1962), including a period as President of the latter from 1961–1962. He served as a consultant to a wide variety of national bodies including the National Science Foundation, National Institutes of Health, Department of Interior, and Department of the Navy. He served as Director of the International Indian Ocean Expedition from 1963–1967, on the U.S. Marine Mammal Commission, the National Academy of Sciences, National Research Council, International Atlantic Salmon Foundation, International Council for the Exploration of the Sea, and on the editorial boards of numerous prestigious journals. Always in the forefront of international relations, John was a member of the U.S. Delegation of Oceanographers to the People's Republic of China in 1978 and the National Science Foundation Biologic Oceanographic Delegation to South Korea in 1979.

John's contributions to the world of aquaculture have been many, varying from macrophyte culture to waste-recycling aquaculture systems involving multispecies polyculture. Although this work was initiated over 25 years ago, variants on that same theme remain central to current efforts in locations around the world from the United States to Israel—a testament to the originality of his contributions. Of all his contributions, John is probably most familiar to National Shellfisheries Association members for two publications. The first contribution, published in 1962, is the development of f media in collaboration with fellow N.S.A. Honored Life Member Robert R. L. Guillard. Phytoplankton culture is an essential component of larval and juvenile culture as we currently know it, and the development of f media was a milestone in the march toward consistent production of food species for bivalve culture. The second is the major text on aquaculture co-authored with John E. Bardach and William O. McLarney. Published in 1972, this remains a valuable text even today.

I came to know John when serving as a postdoctoral fellow under his mentorship when I first arrived in the United States in late 1975. In addition to his brilliant intellect, John is a caring person with an infectious laugh and a love of life that he infuses in all who are exposed to him for any period. He retains an active interest in marine science and, as demonstrated to me on a recent visit to his Massachusetts home, still articulates challenging and innovative questions on a wide range of current research efforts from larval fish development on Georges Bank to macrophyte culture for industrial purposes. I consider myself very fortunate to have worked with him during my career.

INFLUENCE OF FOOD SUPPLY ON POSTMETAMORPHIC GROWTH AND SURVIVAL OF HATCHERY-PRODUCED LION'S PAW SCALLOP, *NODIPECTEN NODOSUS* (LINNAEUS, 1758)

GUILHERME S. RUPP,¹* RAYMOND J. THOMPSON,¹ AND G. JAY PARSONS²†

¹Ocean Sciences Centre, Memorial University of Newfoundland, St. John's, NL, Canada A1C 5S7;

²Fisheries and Marine Institute, Memorial University of Newfoundland, St. John's, NL, Canada A1C 5R3.

ABSTRACT Poor growth and low survival are often reported in hatchery-reared scallops early after settlement and metamorphosis. The effects of algal deprivation, substrate biofilm, and two algal cell concentrations (ca. 4.7×10^3 and 4×10^4 cells mL⁻¹) on growth and survival were investigated during 9 days after settlement in experiment 1, and the effects of the two algal concentrations were examined for 16 days post-set in experiment 2. In experiment 1, the presence of a biofilm on the collectors significantly enhanced postlarval settlement, but not growth. Five days after settlement, at a shell height of about 250 μ m, postlarvae fed a low algal concentration were significantly larger than postlarvae in the other treatments (unfed, biofilm-covered collectors and high algal concentration), which attained similar sizes. Nine days post-set, postlarvae fed at higher algal concentration were larger than postlarvae to which no suspended algae were supplied but were smaller than those cultured at low food concentration. Reserves accumulated during the larval stage were sufficient to sustain metamorphosis. Limited shell growth, and high survival in the absence of exogenous food, giving no indications of food deprivation-induced mortality for at least 9 days post-set. In experiment 2, 10 days after settlement, postlarvae cultured at 4.7×10^3 cells mL⁻¹ were larger than postlarvae cultured at 4×10^4 cells mL⁻¹, but after 16 days post-set, postlarvae in both treatments attained similar shell height. Between 10 and 16 days after settlement (shell height ca. 300–400 μ m), feeding demand of postlarval *Nodipecten nodosus* significantly increased, as demonstrated by a sharp increase of gut pigment concentration, which was probably related to key events in the gill morphogenesis. Mortality, on the contrary, was higher at 4×10^4 cells mL⁻¹ than at 4.7×10^3 cells mL⁻¹. An alternative explanation to the high mortality of scallops often recorded early after metamorphosis in aquaculture settings, other than the depletion of endogenous reserves, is proposed. Food demand of postlarval *N. nodosus* is less than usually supplied in scallop hatcheries, and growth can be significantly increased early after settlement by adjusting the algal cell concentration.

KEY WORDS: biofilm, food, growth, hatchery, metamorphosis, *Nodipecten nodosus*, spat settlement

INTRODUCTION

Bivalve mollusks undergo important morphologic and physiologic changes upon completion of larval development, when the planktonic environment is abandoned and benthic life is assumed (Burke 1983). Metamorphosis is an energetically demanding process, and after the loss of the larval velum there is a cessation of filter-feeding capability until the postlarval ctenidia become functional (Bayne 1965, Hodgson & Burke 1988, Sastry 1965). During metamorphosis, the biochemical reserves used can be neutral lipids (Holland & Spencer 1973), proteins (Rodriguez et al. 1990), both proteins and lipids (Lu et al. 1999, Whyte et al. 1992), or proteins, lipids, and carbohydrates (Farias et al. 1998, Videla et al. 1998), although the energetic contribution of the carbohydrates is minor. Postmetamorphic shell growth of bivalves relies initially on endogenous reserves accumulated during larval life, and subsequent growth and survival are believed to depend on efficient acquisition of exogenous food before endogenous energy reserves are depleted (Whyte et al. 1992).

Though suspension feeding begins early in postmetamorphic oysters (Reid et al. 1992), which rapidly develop functional gills within a few hours after attachment (Baker & Mann 1994), in pectinids it is not clear when suspension feeding commences after metamorphosis. The anatomy of the gills of adult scallops differs

from that of other groups of bivalves due to the highly reduced latero-frontal cirri (Beninger 1991, Beninger & Le Penneec 1991), suggesting that scallops are not as efficient as other lamellibranchs in capturing small particles (<5–7 μ m) (Mohlenberg & Riisgard 1978, Palmer & Williams 1980). In addition, it is not clear if during postlarval stages, the efficiency in capturing small particles is also reduced. Gills of postlarval *Pecten maximus* at a shell height of 0.25–0.9 mm are believed to be partly functional (Beninger et al. 1994). The development of gills of postlarval *Placopecten magellanicus* is more protracted than in other bivalves, so that suspension feeding is probably inefficient in spat less than 1–2 mm in shell height (Veniot et al. 2003). According to Reid et al. (1992), effective suspension feeding in *Patinopecten yessoensis* starts one week after metamorphosis at a size of 400 μ m, when the supra- and infrabranchial chambers are formed. Some bivalves also use a transitional phase of pedal feeding, which allows detritus and benthic diatoms to be ingested, bridging the nutritional gap until suspension feeding becomes effective (Reid et al. 1992). Pedal feeding involves collection of epiflora by protrusion of the ciliated foot, which is then withdrawn into the mantle cavity, where benthic particles adhering to the cilia are transferred to the palps and then carried to the mouth (Reid et al. 1992). Pedal feeding is an important feeding mode for up to 12 wk after metamorphosis in the geoduck *Panope abrupta* (King 1986). It has also been documented in the scallop *Patinopecten yessoensis* at sizes <350 μ m, but in larger spat its nutritional contribution is not clear (O'Foighil et al. 1990, Reid et al. 1992). The uptake of dissolved organic matter (DOM) is also an alternative mode of nutrition, for bivalve larvae and spat, but its energetic contribution is considered low (Manahan 1983).

The period from metamorphosis to a size of 0.5 mm is critical

for successful production of scallops in hatchery/nursery culture, where high mortalities have been recorded for the lion's paw scallop, *Nodipecten nodosus* (pers. obs.), as well as for other scallops (Abarca 2001, Bourne & Hodgson 1991, Bourne et al. 1989, Castagna & Duggan 1971, O'Foighil et al. 1990, Uriarte et al. 2001). Nevertheless, only few studies have focused on the influence of food on growth and survival of scallops within this size range (Nicolas & Robert 2001, O'Foighil et al. 1990). The causes of high mortality of postlarval scallops in hatcheries remain unclear. It has been suggested that depletion of endogenous reserves before exogenous food intake can meet the energetic demands of growth, and metabolism may explain these mortalities (O'Foighil et al. 1990, Whyte et al. 1992).

The body size at which suspension feeding becomes an important mechanism supporting shell growth during early postlarval life of *N. nodosus* is not known. Neither is it clear to what extent shell growth relies exclusively on endogenous food reserves, nor is it known whether pedal feeding is an important mechanism of food intake during early postlarval life.

The lion's paw scallop *N. nodosus* has great potential as an aquaculture species in Brazil, and due to insufficient wild spat collection (Rupp 1994), hatchery production of juveniles is the only source of spat for aquaculture development. Therefore, optimization of growth and survival during hatchery/nursery production will be essential for the establishment of scallop aquaculture. Considering the uncertainty about the feeding capabilities of early postlarval scallops, the objectives of the current study were to examine the influence of food availability on growth and survival of *N. nodosus* immediately after metamorphosis (0.2–0.4-mm shell height) and to determine the size at which availability of exogenous food begins to support growth and survival.

Postlarval growth and survival of *N. nodosus* were determined in two experiments when presence or absence of epiflora and suspended food at different concentrations were tested. It was hypothesized that if early postlarvae are not able to acquire food by suspension feeding due to delayed anatomic development of the gills, then growth would depend on endogenous food reserves or on food uptake by pedal feeding. If growth depended solely on endogenous reserves, then it would be identical in the presence or absence of exogenous food sources. Conversely, if postlarvae benefited nutritionally from bacteria and benthic microalgae by pedal feeding, then growth would be higher when they are on substrates covered by a biofilm, compared with unfed animals. Furthermore, if endogenous energy was depleted in scallops deprived of food, a significant mortality should occur. After the gills become functional, growth would be higher in postlarvae fed with algae. Additionally, postlarval growth, ingestion, and survival were determined at two algal concentrations.

MATERIALS AND METHODS

General Procedures

Larval Rearing

Larval rearing and postlarval culture experiments were undertaken at the Laboratory for the Culture of Marine Molluscs – Federal University of Santa Catarina (LCMM – UFSC), in Florianópolis, Santa Catarina State, Brazil. Broodstock (shell height, 11–12 cm) were collected in the wild by scuba diving and maintained in lantern nets off João da Cunha island (Porto Belo, SC) until transfer to the laboratory 14 days before the scallops were

induced to spawn. Scallops were maintained in tanks with flowing seawater at a temperature of 17–18°C and were fed a mixture of cultured microalgae (*Isochrysis* sp. (clone T-iso), *Chaetoceros calcitrans*, *C. muelleri*) at final concentrations of 4 to 6 × 10⁴ cells mL⁻¹. Such conditions produce successful spawnings, resulting in large numbers of oocytes (Rupp et al. 1997). To induce spawning, scallops were first immersed for 1 h in UV-irradiated filtered seawater (UV-FSW) with a high concentration (ca. 5 × 10⁵ cells mL⁻¹) of *Isochrysis* sp. (clone T-iso). They were then placed in flowing UV-FSW, and the water temperature was increased from 18 to 26°C over 3 h (Rupp 1994). As soon as gametes started to be released, individual scallops were separated in different containers. *N. nodosus* is a functional hermaphrodite, and the spawning scallops were frequently transferred to a new container to avoid mixing the different gametes, therefore minimizing self-fertilization. Fertilization was carried out using sperm and eggs released by different individuals (pooled from several individuals). Two batches of larvae were raised using scallop hatchery techniques (Rupp 1994, Uriarte et al. 2001) in 2000-L polyethylene tanks at densities starting at 10 larvae mL⁻¹ and ending at 1–2 larvae mL⁻¹. Seawater was filtered (1 µm) and UV-irradiated, salinity was 33‰, and temperature was maintained at 23–24°C. Water was changed daily, and a mix (1:2:1) of *Isochrysis* sp. (clone T-iso), *C. calcitrans*, and *C. muelleri* (formerly *C. gracilis*, CHAGRA – Provasoli-Guillard CCMP Laboratory) in final concentrations of 1 × 10⁴ to 3 × 10⁴ cells mL⁻¹ was supplied daily. Algae were cultured in 100-L plastic bags in Guillard "F/2"-modified media under fluorescent light. Bacterial proliferation was controlled by addition of chloramphenicol (1 mg L⁻¹) to the larval cultures.

Settlement

When larvae (pediveligers) displayed morphologic and behavioral characteristics indicating competence (conspicuous eyespot, well-developed foot, aggregation in clumps, forming mucous strands, and crawling behavior) and attained a mean shell length of ca. 200 µm (shell height, 185–190 µm), they were considered competent to undergo metamorphosis. Pediveligers were then retained on a 140-µm-mesh Nytex screen, subsampled, counted in a Sedgwick-Rafter chamber using a microscope, and then transferred to 100-L tanks (experimental treatments) at a stocking density of 1 larva mL⁻¹. Water was changed daily, and no antibiotic was used during the experiments. The collectors used for larval settlement were polyethylene screens (mesh size, 3 mm), which in previous experiments resulted in high settlement of spat and were convenient to manipulate for experimental purposes. The collectors were cut into rectangles (25 × 50 cm), and the edges of the longer sides were tied together, so that they assumed a cylindrical shape. During water changes, postlarval scallops in the bottom of setting tanks were collected and observed under a dissecting microscope. When present, these assemblages were composed mainly of dead scallops and were removed. As well, any remaining unsettled larvae were removed from the experimental units 72 h from initiation of the experiment, so that variability in postlarval size was minimized. Scallops displaying conspicuous dissoconch shell were considered to have undergone metamorphosis and settlement.

Experiment 1

In experiment 1, four treatments were carried out in duplicate 100-L tanks. Treatments consisted of (a) no algae supplied, (b) no

algae supplied, but the collectors had previously been immersed in coarse-filtered seawater (sand filter ca. 100 μm) for 8 days to allow growth of an epiflora of bacteria and benthic microalgae, (c) a mixed algal diet consisting of *Isochrysis* sp. (clone T-iso) and *C. muelleri* (1:1) at a final concentration of 4×10^4 cells mL^{-1} , supplied daily after the water change, and (d) the same volume of algal culture supplied in treatment (c) but with a cell concentration reduced by 90% by gravity filtration using cellulose paper filter. This procedure resulted in a final algal concentration of 4 to 5×10^3 cells mL^{-1} (mean, 4.7×10^3 cells mL^{-1}) while keeping the volume of the culture and concentrations of dissolved nutrients the same as in treatment (c). Preliminary observations indicated that algal cells were intact after filtration. Algal cells were counted with a Coulter counter model Z1. Algal cultures in the exponential growth phase were supplied daily to treatments (c) and (d) at volumes of ca. 0.3–0.4 L of each species. Treatments (a), (b), (c), and (d) will hereafter be referred to as unfed (U), epiflora (E), high algal concentration (H), and low algal concentration (L), respectively. Swimming larvae were retained during water changes and returned to the experimental units until day 3 postsettlement, when they were removed, to reduce size variability of settled postlarvae. To determine shell height (distance from the umbo to the ventral margin of the shell), samples were taken of setting larvae and of spat at 3 days (1 collector/tank), 5 days (3 collectors/tank), and 9 days (3 collectors/tank) postsettlement, when postlarvae were detached from the collectors. Both sides of the collectors were then thoroughly brushed with repeated gentle movements inside plastic trays filled with filtered seawater. This procedure was repeated four times, until no more spat were retrieved from the collectors. Detached spat were then screened, separated from debris, and preserved in 4% buffered formaldehyde in filtered seawater for further counting and measurements.

Water temperature was maintained at 23°C (SD \pm 0.5°C) and salinity at 33‰. Sampling to determine larval survival was carried out 5 and 9 days postsettlement (4 collectors/tank each day). Postlarval samples were preserved in 4% buffered formaldehyde in seawater. Shell heights were measured with an ocular micrometer using a binocular microscope.

Experiment 2

In experiment 2, treatments consisted of spat fed daily at concentrations equal to those in treatments (H) and (L), as previously described for experiment 1. Each treatment was carried out in duplicate 200-L tanks. General procedures were the same as for experiment 1, but extended until 16 days postsettlement. In this experiment, addition of algal diets started 3 days after settlement. Water temperature was maintained at 25°C (SD \pm 0.5) and salinity at 33‰. Postlarval shell height (2 collectors/tank each day) and survival (6 collectors/tank) were determined on days 3, 10, and 16 post-set. In addition, shell height (maximum dorso-ventral dimension perpendicular to the hinge) and shell length (maximum antero-posterior dimension, parallel to the hinge) were measured ($n = 120$) to determine the relationship between shell dimensions.

Gut Pigments

To determine ingestion of microalgae by the scallops, the pigment content in the guts of larvae and postlarvae was determined by the gut fluorescence technique (Yentsch & Menzel 1963), which is frequently used to determine pigment content in meso- and macrozooplankton (>200 μm) (Bamstedt et al. 2000). Larvae

($n = 100$ –200) were sampled at settlement and at day 1 post-set. Postlarvae were sampled at 5, 10, and 16 days postsettlement, when they were detached from the collectors, counted, and thoroughly rinsed in FSW while retained in a 140- μm mesh screen (Nalgene filter). Pigments were extracted on 90% acetone at 4°C for 24 h. Fluorescence was determined with a Turner digital fluorometer (TD 10-AU), with readings taken before and after acidification with 10% HCl. The concentrations of chlorophyll *a* and phaeopigments (mainly phaeophytin and phaeophorbide) were calculated following Bamstedt et al. (2000). Because ingested chlorophyll *a* is rapidly degraded and converted into phaeopigments (Dagg & Wyman 1983), the total pigment content in the guts of postlarval scallops was calculated as the sum of chlorophyll *a* and phaeopigments.

Data Analyses

Data were analyzed with the SPSS statistical package (version 10). For experiment 1, nested ANOVAs ($\alpha = 0.05$) were first carried out to determine the significance of differences in postlarval shell height among collectors within a tank and among tanks within a treatment, which were both found to be not significant. One-way ANOVAs were then carried out after pooling the tank and collector data within a given treatment, with treatment as the main factor. Residuals were checked graphically for normality and homoscedasticity (Sokal & Rohlf 1995), and the assumptions for ANOVA were not violated. When significant differences were detected among means ($\alpha = 0.05$), a *post hoc* Tukey-B test was performed. In experiment 2, independent samples Student's *t* tests were carried out to determine differences between treatments. The number of postlarvae attached to the collectors was compared among treatments by one-way ANOVA and independent samples Student's *t* test for experiments 1 and 2, respectively. Linear regression was used to describe the relationship between postlarval shell height and length.

RESULTS

Experiment 1

Growth

The mean shell height of setting pediveligers was 187 μm (SE = 0.8) (shell length, 200.8 μm). Three days after settlement, mean shell height for all treatments ranged from 197.2 to 199.1 μm , and there were no significant differences among treatments (one-way ANOVA, $F = 0.038$; $df = 3,236$; $P = 0.99$) (Fig. 1). Five days after settlement, there were significant differences in post-larval shell height among treatments (one-way ANOVA, $F = 28.68$; $df = 3,716$; $P < 0.001$). Postlarvae fed at low algal concentration (L) attained a mean shell height of 247.2 μm (SE = 2.2), which was significantly greater than in the other treatments. Nine days after settlement, there were also significant differences in shell height among treatments (one-way ANOVA, $F = 155.3$; $df = 3,716$; $P < 0.001$). Postlarvae fed at low algal concentration (L) attained a mean shell height of 333.6 μm (SE = 4.85), which was again significantly greater than for postlarvae exposed to the other treatments (Tukey-B). Furthermore, postlarvae cultured at high ration (H) (mean shell height 284.5 μm , SE = 3.35) attained a significantly greater shell height than those in the treatments unfed (U) (mean shell height 246.1 μm , SE = 2.61) and epiflora (E) (mean shell height 241.8 μm , SE = 2.27) (Tukey-B). Postlarvae in the treatments (E) and (U) displayed similar shell heights (Tukey-B).

Figure 1. Shell heights (μm) of setting pediveligers (day = 0) and post-larvae 3, 5, and 9 days after settlement, cultured under four treatments (H = high algal concentration, L = low algal concentration, E = collectors covered by epiflora, U = no algae supplied) (mean \pm SE). (For each day, different letters denote significant differences.)

Daily growth rates from day 3 to day 9 were 22.61, 14.49, 7.43, and 8.15 $\mu\text{m day}^{-1}$ for the treatments L, H, E, and U, respectively.

Survival

The mean number of postlarvae attached to the collectors 5 days after settlement ranged from 166 (SE = 46) in the low food concentration (L) treatment to 369 (SE = 92) in the epiflora treatment (E) (Fig. 2). There were significant differences among treatments (one-way ANOVA, $F = 6.71$; $df = 3, 28$; $P = 0.001$). Collectors covered by an epiflora (E) had significantly more scallops than the other treatments, which were statistically similar to each other (Tukey-B). On average, 78 to 120% more postlarvae settled on the epiflora-covered collectors than on those in the other treatments. On day 9, there were also significantly more postlarvae on the collectors in the epiflora treatment. Overall, there was a decrease of about 26.8% in the number of spat attached to the collectors from day 5 to 9, and the percent loss of spat from the collectors did not differ among treatments (one-way ANOVA, $F = 0.57$; $df = 3, 7$; $P = 0.67$).

Figure 2. Number of postlarvae attached to collectors 5 and 9 days after settlement, cultured under four treatments (H = high algal concentration, L = low algal concentration, E = collectors covered by epiflora, U = no algae supplied) (mean \pm SE). (For each sampling date, different letters denote significant differences.)

Experiment 2

Growth

Setting larvae had a mean shell height of 190.7 μm (SE = 0.8) (shell length, 202.6 μm). Three days after settlement, mean post-larval shell height was 205.0 μm (SE = 1.67) and 208.1 μm (SE = 1.97) for the treatments of low algal concentration (L) and high algal concentration (H) respectively, which were statistically similar (t test, $t = -1.42$; $df = 238$; $P = 0.255$) (Fig. 3). On the other hand, 10 days after settlement, postlarvae from treatment (L) had attained a significantly greater shell height (mean = 320.2 μm , SE = 5.29) than those from treatment (H) (mean = 295.0 μm , SE = 4.07) (t test, $t = -3.76$; $df = 238$; $P < 0.001$). After 16 days, mean shell heights were 401.08 μm (SE = 7.24) and 403.17 μm (SE = 7.44) for treatments (L) and (H) respectively, which were statistically similar (t test, $t = 0.2$; $df = 238$; $P = 0.84$). Daily growth rates from days 3 to 10 were 16.02 and 12.85 $\mu\text{m days}^{-1}$, respectively, for treatments (L) and (H), and 13.48 and 18.03 $\mu\text{m days}^{-1}$ from days 10 to 16, respectively.

The relationship between shell height (SH) and length (SL) of postlarval *N. nodosus* had the following linear equation, $\text{SH} = 0.83 \text{ SL} + 13.48$ ($n = 120$, $r^2 = 0.96$) (Fig. 4), which was highly significant (ANOVA, $F = 2488$; $df = 1, 119$; $P < 0.001$). This equation is provided as a useful means of comparison of shell dimension with other studies in which sizes are presented as shell length.

Survival

The mean numbers of postlarvae attached per collector in treatment H were 397.6, 237.5, and 176.3 for days 3, 10, and 16, respectively (Fig. 5). In treatment L, the mean numbers of postlarvae attached per collector were 482.5, 447.1, and 445.4 for days 3, 10, and 16, respectively. While there was no statistically significant difference in the number of spat/collector between treatments at day 3, in subsequent days the number of postlarvae in treatment L was significantly higher than in treatment H. In treatment L, loss of postlarvae from days 3 to 16 was 7% whereas in treatment H the loss was 55%.

Gut Pigments

Total pigments in the gut of larvae decreased from 108.7 ng ind^{-1} to 48 ng ind^{-1} after 24 h in the absence of suspended food,

Figure 3. Shell heights (μm) of setting pediveligers (day = 0) and post-larvae 3, 10, and 16 days after settlement, cultured under two treatments (H = high algal concentration, L = low algal concentration) (mean \pm SE). (Different letters denote significant differences.)

Figure 4. Relationship between shell height (SH) and shell length (SL) of postlarval *Nodiplecten nodosus* ($P < 0.001$).

Figure 6. Pigment content (ng postlarva^{-1}) determined by gut fluorescence of postlarvae cultured under two treatments (H = high algal concentration, L = low algal concentration) after 1, 5, 10, and 16 days postsettlement (mean \pm SE). (Different letters denote significant differences.)

as algae were not supplied until 3 days postsettlement (Fig. 6). Five days after settlement, however, postlarvae had a higher pigment content in the gut than in the previous sample, both in treatment H ($143.3 \text{ ng ind}^{-1}$) and in treatment L ($170.48 \text{ ng ind}^{-1}$), which were similar (t test, $t = -1.39$; $df = 6$; $P = 0.1$). Ten days after settlement, postlarvae in treatment H displayed a slightly higher gut pigment content ($316.11 \text{ ng ind}^{-1}$) than those in treatment L ($212.42 \text{ ng ind}^{-1}$) (t test, $t = 1.99$; $df = 6$; $P = 0.048$). Subsequently, at 16 days post-set, the pigment content in postlarvae from treatment H ($1307.6 \text{ ng ind}^{-1}$) was significantly higher in treatment L ($462.5 \text{ ng ind}^{-1}$) (t test, $t = 4.54$; $df = 5$; $P = 0.003$).

DISCUSSION

This study focused on shell growth of *N. nodosus* shortly after settlement. Growth in juvenile bivalves occurs when energy acquisition exceeds metabolic demand to sustain basic physiologic processes, as there is no energy allocation to reproduction. In scallops, active suspension feeding on phytoplankton is the major form of food acquisition (Bricelj & Shumway 1991). During post-

larval life, bivalves exhibit fast shell growth rates, which are not accompanied by a proportional increase in biomass. This growth pattern may be a protective adaptation of all bivalves, to reduce susceptibility to predation (Holland & Spencer 1973, Lu & Blake 1996, Whyte et al. 1992). In the current study, therefore, it is assumed that shell growth of postlarval scallops is maximized after the onset of acquisition and use of exogenous food.

There was a significant increase in postlarval shell height ($\Delta = 10$ to $13 \mu\text{m}$) from settlement to 3 days post-set in all treatments from experiment 1, regardless of the availability of exogenous food. The presence of a biofilm, suspended algae, or dissolved organic matter associated with the algal cultures did not result in faster shell growth than in the unfed control up to 3 days. These results demonstrate that shell growth of *N. nodosus* immediately after metamorphosis is not dependent on exogenous food, but fueled by endogenous reserves accumulated during larval life. This was also demonstrated in both treatments of experiment 2, when algae were not supplied for the first 72 h. Although the complete nutritional requirements of *N. nodosus* larvae remain unknown, the mixed diet consisting of the flagellate *Isochrysis* sp. (clone T-iso) and the diatoms *C. calcitrans* and *C. muelleri* (= *C. gracilis*) used during larval culture is widely used in scallop hatcheries, supporting significant growth and providing a balanced biochemical composition for larvae (Bourne et al. 1989, Farias 2001, Uriarte et al. 2001). In this study, *N. nodosus* pediveligers accumulated sufficient energy reserves to accomplish metamorphosis in the absence of exogenous food. In a study by Lu et al. (1999), *Argopecten irradians* was able to complete metamorphosis when deprived of food, and energy losses accounted for 57.9% of the total organic reserves. *Ostrea chilensis* pediveligers catabolized 65.5% of their energy reserves (Videla et al. 1998).

Five days after settlement, growth of postlarvae was significantly higher at low algal concentration (ca. $4.7 \times 10^3 \text{ cells mL}^{-1}$) than in the other treatments. This indicates that postlarval *N. nodosus* at a shell height between 200 and 250 μm (days 3–5) can already capture and use phytoplankton as a food source; therefore, the gills are already capable of capturing particles. Furthermore, 9 days after settlement, postlarvae were larger when fed at low algal concentration than at high concentration ($4 \times 10^4 \text{ cells mL}^{-1}$). Algal cell concentrations fed to postlarval scallops in hatcheries

Figure 5. Number of postlarvae attached to the collectors 3, 10, and 16 days after settlement, cultured under two treatments (H = high algal concentration, L = low algal concentration) (mean \pm SE). (Different letters denote significant differences.)

usually range from 2.0 to 2.5×10^4 cells mL^{-1} (Bourne et al. 1989), 3.5×10^4 cells mL^{-1} (Dabinett et al. 1999), to 8.0 to 10×10^4 cells mL^{-1} (examples in Uriarte et al. 2001). The current results indicate that the feeding requirement of *N. nodosus* immediately after metamorphosis is very low, and that high algal concentrations hinder growth of postlarvae smaller than ca. 350 μm . High algal concentration inhibits filtration in bivalve larvae (Gerdes 1983, Riisgard 1988, Sprung 1984). In juveniles and adults the gills are completely functional, and feeding activity can be controlled at high particle concentrations by discontinuous feeding behavior, reduction of clearance rate, or increasing pseudofaeces production (Bricelj & Shumway 1991). However, none of these mechanisms has been demonstrated in postlarval scallops smaller than 0.5 mm in shell height, in which the gills are not fully developed (Beninger et al. 1994, Veniot et al. 2003). The current study suggests that high algal concentrations may physiologically stress the scallops, preventing them from fully exploiting their growth potential. Riisgard (1991) postulated that low growth rates of bivalves recorded in laboratories may partly be due to unnaturally high algal concentrations, which lead to suboptimal conditions (valve closure, reduced metabolism, and reduced biosynthesis). Two other studies on postlarval scallops reported optimum thresholds for growth at low concentrations: 1.0 to 2.0×10^4 cells mL^{-1} for *Argopecten irradians* (Lu & Blake 1996) and 0.7 to 1.7×10^4 cells mL^{-1} for *Pecten maximus* larger than 0.5 mm (Nicolas & Robert 2001).

Nine days after settlement, postlarvae from the epiflora and unfed treatments had reached the same size and were significantly smaller than fed postlarvae. Surfaces immersed in seawater are rapidly colonized by bacteria and subsequently by diatoms and protozoans (Corpe 1970). Thus, the provision of biofilm-colonized substrates provided no nutritional benefit for *N. nodosus* for up to 9 days after settlement. These results suggest that pedal feeding, if indeed it does occur, makes a negligible contribution to growth of *N. nodosus*. It is also possible that the algae growing on the collectors were too large to be ingested by postlarval scallops or had no nutritional value. Microalgal assemblages on the collectors in this study were dominated by *Melosira* sp., a cosmopolitan non-planktonic chain-forming diatom (Hasle & Syvertsen 1997) that had individual cell size of ca. 25–30 μm but formed large chains (>300 μm). Although *Melosira* sp. is an abundant diatom in the gut contents of adult scallops (*Argopecten irradians*) (Davis & Marshall 1961) and *Placopecten magellanicus* (Shumway et al. 1987), it was probably not ingested by postlarval *N. nodosus* either due to the large size of the chains or absence of pedal feeding behavior. Within pectinids, pedal feeding has been reported only in *Patinopecten yessoensis* as a vestigial behavior, and its nutritional contribution is much less than suspended algae and limited to the first week after settlement (O'Foighil et al. 1990, Reid et al. 1992). If pedal feeding is a general mechanism in scallops, the suitability of different species of epibenthic algae that could be induced to grow on the collectors remains an interesting area for future investigations, which could contribute to optimization of postlarval growth.

Although the presence of epiflora on the collectors did not enhance growth of postlarval *N. nodosus*, it significantly increased settlement success, leading to 78–120% more postlarvae on the fouled collectors. Increased settlement induced by the presence of a biofilm has been demonstrated for some bivalves, including the scallops *Patinopecten yessoensis* (O'Foighil et al. 1990), *Chlamys hastata* (Hodgson & Bourne 1988), and *Placopecten magellanicus*

(Parsons et al. 1993), although in *Pecten maximus* a certain bacterial film did not influence settlement (Trittar et al. 1992). The effects of biofilms on settlement of *N. nodosus* have not previously been studied, and the current results have direct implications for the optimization of hatchery production. The immersion of the spat collectors in seawater to allow the formation of a biofilm is therefore a recommended hatchery practice.

There was an increment in shell height of 55–60 μm in the unfed and epiflora treatments, which was probably sustained by endogenous reserves, as the concentration of food particles in the water was negligible and tanks were covered to prevent entry of light, thus minimizing uncontrolled algal growth. Furthermore, mortality in these treatments did not differ from the fed group, suggesting no significant effect of food availability on survivorship during this period. Although survival beyond 9 days post-set was not followed, it is clear that the energy accumulated during the larval phase was sufficient to supply energy for maintenance for at least 9 days after settlement. Considering that acquisition and use of suspended food began 3 to 5 days after metamorphosis, the energy reserves accumulated during the larval period were sufficient to meet the demands of metabolism and growth of *N. nodosus* during the period in which there was no suspension feeding. In contrast to the rock scallop (*Crassodoma gigantea*), in which pediveligers had high mortality during 4 days of starvation (Whyte et al. 1992), *N. nodosus* not only survived, but also metamorphosed and displayed limited shell growth in the absence of algal food for at least 9 days post-settlement.

According to Whyte et al. (1992), the fatty acid profile of postlarval scallops *Crassodoma gigantea* indicate food assimilation at 25 days after metamorphosis, but their calculations suggest that before this, the acquisition of exogenous energy is not sufficient to meet the metabolic demand for growth, although earlier postlarvae were not analyzed. Postlarval mortality of *C. gigantea* was explained by insufficient acquisition of exogenous food soon after metamorphosis to meet the energetic demands of shell growth, which was postulated to be unimpeded by total energy depletion. The results of the current study, however, clearly indicate that shell growth of *N. nodosus* postlarvae is inhibited by the absence of suspended food compared with fed postlarvae, suggesting that energy acquisition from exogenous sources is a limiting factor for shell growth, and endogenous energy is not indiscriminately allocated to growth. Restrained growth in the absence of food may be a strategy to prolong survival under unfavorable conditions. If postlarval growth had been unimpeded until all endogenous energy was depleted, then mortality, not reduction in growth, would have been observed in the unfed treatment. The current results gave no indication of mortality induced by deprivation of suspended food for up to 9 days postsettlement, and food acquisition started well before endogenous energy was depleted. It is possible that the tropical scallop *N. nodosus* develops more rapidly than temperate species, such that the gills become functional earlier, being capable of capturing suspended particles at a smaller body size (200–250 μm shell height) than *Patinopecten yessoensis*, in which effective suspension feeding begins at 400 μm (Reid et al. 1992), or than *Crassodoma gigantea*, two temperate water species. Indeed, Barré et al. (2002), comparing morphologic development of the cold-water *Placopecten magellanicus* and the warm-water *Argopecten irradians*, concluded that key events in gill development occurred at a smaller size in *A. irradians*, indicating inter-specific variability in gill ontogeny within pectinids.

Manahan (1983) demonstrated that filtrates from algal cultures (*Thalassiosira pseudonana*) contained large concentrations of dissolved free amino acids, which could be taken up by bivalves. In the current study, the same volume of algal culture media was added for both treatments of high and low food concentrations, but reducing the algal cell density by means of filtration in the latter treatment. This approach ensured that bacteria and concentrations of dissolved nutrients in the algal culture media, as well as exuded dissolved polymers and free amino-acids released by microalgae, which could have nutritional value for bivalves, were similar in both high and low food concentration treatments. Therefore, the only factor differing between treatments was the concentration of algal cells supplied, and any differential contribution of DOM among the treatments in which food was supplied was eliminated.

In experiment 2, after 10 days from settlement, postlarvae cultured at low algal concentration had shell heights significantly larger than those in the other treatments, consistent with experiment 1. However, 16 days after settlement, the shell heights of postlarval scallops were similar between treatments. The increase in the gut pigment content from settlement to day 5 post-set further confirms that at day 5, scallops were already able to ingest phytoplankton. Furthermore, at day 10, the pigment concentration was slightly higher in the scallops cultured at high algal concentration. As growth rates from days 3 to 10 were higher in the scallops cultured at low concentration, postlarvae used food more efficiently at low concentrations, as previously discussed. The current results suggest that there was an increase in food uptake around day 10 at ca. 300 μm shell height, but this increase in ingestion was not immediately reflected in growth, but in the subsequent period, when postlarvae cultured at high algal concentration displayed higher growth rates than those cultured at the low concentration. The sharp increase in the gut pigment of postlarvae from the high concentration treatment from days 10 to 16 suggests that at 300–400 μm shell height, there is a significant increase in feeding activity, which is probably associated with a critical stage in the gill development, as described for *Placopecten magellanicus* (Veniot et al. 2003) and *Pecten maximus* (Beninger et al. 1994). Postlarvae cultured at low algal concentration also displayed an increase in pigment content, but less than those at high cell concentration. At this point, the availability of food probably became limiting in the low food treatment, and ingestion of algae was therefore lower, but not resulting in immediate differences in shell height among treatments. Two nonexclusive hypotheses can be proposed to explain this result. First, because there is a lag between food acquisition, digestion, assimilation, and the shell growth response, differences in shell heights between treatments would only be apparent after day 16, and faster growth rates were indeed displayed by postlarvae at the high food treatment from days 10 to 16. Second, absorption efficiency tends to decrease at high food concentration, as demonstrated for other bivalves (Griffiths & King 1979, Navarro & Winter 1982, Thompson & Bayne 1974, Yukihiro et al. 1998). Thus, as the capacity of the digestive gland is exceeded, more organic material is rejected in feces. In this manner, even at lower food concentration, postlarval *N. nodosus* could maximize absorption of ingested food and display significant growth, despite lower algal ingestion. The current results suggest that food levels usually supplied to postlarval scallops in hatcheries are higher than the demand, and the high cell concentrations supplied may lead to reduced feeding rate and/or lower absorption efficiency, therefore resulting in a significant waste of cultured microalgae. The current study sets the stage for further

studies on the effect of cell concentration on the feeding physiology of scallop postlarvae, to maximize growth potential soon after settlement. Feeding early postlarvae at an optimum cell concentration of a suitable algal species could increase growth, significantly reduce the time to transfer to the sea-based nursery, and therefore reduce production costs.

Survivorship significantly differed between low and high food treatments in experiment 2, higher mortality being recorded at the higher food level. It is unlikely that the high cell concentration directly caused scallop mortality, but an excess of microalgae may have led to settlement of cells to the bottom of the tank, where they may have stimulated bacterial proliferation and reduced water quality. Nicolas & Robert (2001) also found the lowest mortality in postlarval *Pecten maximus* fed at the lowest food concentration. High bacterial concentration and accumulation of ectometabolites are detrimental to larval and postlarval bivalves (Elston & Leibovitz 1980, Loosanoff & Davis 1963, Prieur et al. 1990). Likewise, larval pectinids are highly susceptible to bacterial infections in hatcheries (Freites et al. 1993, Nicolas et al. 1996, Riquelme et al. 1995, Sainz et al. 1999), being more vulnerable to vibriosis than are larval oysters and penshells (Luna-Gonzales et al. 2002). The relatively immature immune system in larval pectinids compared with other bivalves may explain such differential susceptibility to pathogens (Luna-Gonzales et al. 2002). Although there is a lack of immunology studies of the early life stages of scallops, it is possible that early postmetamorphic scallops have a delayed development of the immune system compared with other bivalves and are therefore more susceptible to bacterial infection in hatcheries.

In conclusion, the current study demonstrated that the presence of epiflora on the collectors significantly increased settlement of the lion's paw scallop, but did not enhance postlarval growth. Furthermore, settlement, metamorphosis, and early postlarval growth were accomplished in the absence of suspended food, but 3–5 days (ca. 200–250 μm) after settlement, the availability of algae was an important factor determining growth of *N. nodosus*, and a low concentration (ca. 4.7×10^3 cells mL^{-1}) of *Isochrysis* sp. (clone T-iso) and *Chaetoceros muelleri* was more advantageous to growth and survival than 4×10^4 cells mL^{-1} . Between 10 and 16 days after settlement (ca. 300–400 μm), feeding demand of postlarval *N. nodosus* significantly increased, as demonstrated by increased gut pigment concentration, which was probably related to key events in the gill morphogenesis. The absence of exogenous food did not limit survival for at least 9 days after settlement, as ingestion of exogenous food started well before that. On the contrary, at high food concentration (4×10^4 cells mL^{-1}), mortality increased. Depletion of endogenous reserves before initiation of suspension feeding did not account for postlarval mortality. Alternatively, an immature immune system in early postlarval scallops, and therefore high susceptibility to disease, may explain the high postlarval mortality often reported in scallop hatcheries.

ACKNOWLEDGMENTS

This research was supported by a CNPq (Conselho Nacional de Desenvolvimento Científico e Tecnológico, Brazil) Ph.D. scholarship to GSR, and the Brazilian Mariculture Linkage Program (BMLP), Canada. The Laboratory for the Culture of Marine Molluscs (LCMM), Federal University of Santa Catarina, is acknowl-

edged for providing experimental facilities and personnel assistance. We particularly thank Micheline M. de Bem for carrying out the larval cultures, Michella Fuck for helping out during the ex-

periments, and Drs. Pat Dabinett, Sandra E. Shumway, David Innes, and Don Deibel for valuable suggestions on an earlier version of the manuscript.

BIOCHEMICAL COMPOSITION, REPRODUCTIVE ACTIVITY AND FOOD AVAILABILITY OF THE LION'S PAW SCALLOP *NODIPECTEN SUBNODOSUS* IN THE LAGUNA OJO DE LIEBRE, BAJA CALIFORNIA SUR, MEXICO

M. ARELLANO-MARTÍNEZ,^{1,*} I. S. RACOTTA,² B. P. CEBALLOS-VÁZQUEZ,¹ AND J. F. ELORDUY-GARAY¹

¹Centro Interdisciplinario de Ciencias Marinas, Instituto Politécnico Nacional, La Paz, Baja California Sur 23000, México; ²Centro de Investigaciones Biológicas del Noroeste, La Paz, Baja California Sur 23000, México

ABSTRACT The relationships between the nutrient storage cycle, reproductive activity, and available food for the lion's paw scallop *Nodipecten subnodosus* were investigated during a one-year period in Laguna Ojo de Liebre, Baja California Sur, Mexico. Based on histologic data, this study showed that the reproductive cycle of *N. subnodosus* could be divided in four periods: (1) period of quiescence from December to March (with a small reproductive activity in February–March), (2) period of initial reproductive activity from April to May, (3) period of maximum ripeness from June to September, and (4) period of spawning from September to November. The seasonal changes in biochemical composition of somatic tissues of *N. subnodosus* at this locality indicated a clear nutrient storage and use cycle related to reproductive activity. However, the biochemical reserves of adductor muscle, digestive gland, and mantle were used differently over time. Proteins and acylglycerides could be transferred from the testis portion to the ovary portion during the ripening process. We showed that gametogenesis in *N. subnodosus* from Laguna Ojo de Liebre relied on stored reserves, as a consequence of the low food quantity (maximum 1.2 $\mu\text{g L}^{-1}$ chlorophyll *a*) and the low nutritional quality (maximum food index 17%) of the food available for suspension-feeders. The spawning of *N. subnodosus* in Laguna Ojo de Liebre coincided with the chlorophyll *a* maximum concentration, so it appeared to be triggered more by the phytoplankton abundance than by temperature.

KEY WORDS: food availability, *Nodipecten subnodosus*, nutrient transference, reproduction, scallop

INTRODUCTION

The reproductive cycle of marine bivalves is strongly related to nutrient storage and use cycles and environmental parameters such as water temperature and food availability (Giese 1969, Gabbott 1975, Bayne 1976). Gametogenesis is a process that requires energy, and the way to obtain energy differs among species (Park et al. 2001). Some species use the recently ingested energy from the seston (opportunistic species); others use the energy of substrates stored in various organs and tissues (digestive gland, adductor muscle, or mantle) through feeding prior to its gametogenesis (conservative species) (for reviews see Gabbott 1975, Bayne 1976, Barber & Blake 1991). In pectinids, the way in which the substrates are used, and the tissue or organ from which the associated energy is obtained, may vary among species (Ansell 1974, Comely 1974, Taylor & Venn 1979, Epp et al. 1988, Barber & Blake 1991, Martínez 1991, Mathieu & Lubet 1993).

Nodipecten subnodosus is a large pectinid species, reaching a maximum length of 218 mm (Félix-Pico et al. 1999). The lion's paw scallop supports a small commercial fishery only on its northern range of distribution because of its scarce presence in other areas of the Baja California peninsula. The lion's paw is an organism that reaches its commercial size in a relatively short time (Gutiérrez-Villaseñor & Chi-Barragan 1997). Its large adductor muscle is attractive for human consumption, a fact that has important implications for fisheries and aquaculture. However, only a few studies on growth (Carvajal-Rascón 1987, García-Domínguez et al. 1992, García-Pámanes et al. 1994, Barrios 1997, Ortíz-Cuel et al. 1997, Félix-Pico et al. 1999, Racotta et al. 2003) and reproduction (Reinecke-Reyes 1996, Gutiérrez-Villaseñor & Chi-Barragan 1997, Racotta et al. 2003) have been reported.

This study analyzes the seasonal variations in biochemical composition in a wild population of *N. subnodosus* and its relation to their reproductive activity and food availability.

MATERIALS AND METHODS

Animals

Samplings were done in the Laguna Ojo de Liebre (27°55'–27°35' LN and 114°20'–113°50' LW) located in the Mexican Reserve of the Biosphere "El Vizcaíno." From December 2000 to November 2001, 10 lion's paw scallops of 13–16 cm in shell height and 12–15 cm in shell length were collected monthly by divers at 7 m of depth. Scallops were transported alive in a cool and wet environment to lower their metabolism.

In the laboratory, the total and soft body weights and height (largest shell distance in an anterior to posterior orientation) of each scallop were registered to the nearest 0.1 mm using vernier calipers. Scallops were dissected to obtain gonads (without crystalline style and gut content), digestive glands, mantles, and adductor muscles, and their weights were registered and tissues were stored at –80°C for further biochemical analysis. Before freezing, a portion of gonad including both sexes was fixed in a formalin solution (10%) for further histologic analysis.

Indicators of Quantity and Quality of the Available Food

During the study period, seawater samples of the scallop-sampling area were collected using a Van Dorn bottle. The seawater samples were collected at 6.5 m of depth, close to the sandy bottom on which the scallops live. Water was screened through a 200- μm Nitex mesh to eliminate zooplankton and large particles before analysis (Park et al. 2001). For each analysis sample, in triplicate, a known volume of seawater was immediately filtered under gentle vacuum and in dark conditions through washed, pre-combusted, preweighed Whatman GF/F filters (47-mm diameter).

*Corresponding author. Fax: +55 (612) 1225344; E-mail: marellam@ipn.mx

The filters were washed with distilled water to remove residual salt.

Chlorophyll *a* was extracted on acetone, and its concentration was determined using the fluorometric method, as modified by Parsons et al. (1984).

The sum of carbohydrate, lipid, and protein concentration in the water, expressed as a percentage of the total seston, represents a useful index of the quality of the food available to suspension-feeders (Navarro & Thompson 1995). Food quality index (FI) was calculated according to Widdows et al. (1979), using the equation:

$$FI = \frac{FQ}{TPM} \times 100$$

where FQ is the food quantity ($\mu\text{g/L}$), and TPM is the total particulate matter or total seston ($\mu\text{g/L}$).

To calculate FQ, the major biochemical components of seston were analyzed: protein by the method of Lowry et al. (1951), carbohydrates by the phenol-sulfuric acid method (Dubois et al. 1956), and lipids by the sulfophosphovanillin method (Barnes & Blackstock 1973) using a commercial reactive and standard solutions (Merck, Darmstadt, Germany). FQ was then determined as the sum of the concentration of these components.

To calculate TPM, filters were dried at 80°C for 24 h and were reweighed after cooling in a desiccator. TPM was determined as the difference between the filter preweight (before filtering) and the dried filter weight.

Analysis of the Reproductive Activity

Transversal gonad sections including female and male portions were dehydrated in an ethanol series of progressive concentrations and embedded in paraplast X-tra. Sections (7 μm) were obtained and stained with hematoxylin-eosin (Humason 1979). Gametogenesis of *N. subnodosus* was categorized based on the qualitative characteristics of the gonad, separately for each sex, and by considering the five stages of gonadal maturation (undifferentiated, developing, ripe, partially spawned, and spent) proposed by Reinecke-Reyes (1996) for this species. The relative frequencies of the stages of gonadal development throughout the year were obtained with female and male stages combined, as there was not a difference in the temporality pattern between sexes.

To obtain quantitative values that represent the reproductive activity, the monthly gonadosomatic index (GSI) was calculated by dividing the gonad wet weight by the total soft body wet weight and by expressing the results as a percentage (Sastry 1970). Oocyte diameters were measured from digitized images of histologic sections using the SCAN PRO software (version 5.0, Systat Software, Inc., Richmond, CA). Oocytes sectioned through the nucleus were individually traced with the pointer, and the major and minor axis lengths were measured automatically by the software. Then, an average of both dimensions was calculated and considered as the estimated diameter, which was calculated monthly. At least 100 oocytes per scallop were measured. Individuals with few measurable oocytes and extensive phagocytosis ("spent" specimens) were not considered, using the criteria of Grant & Tyler (1983).

Additionally, indices of digestive gland (DGI), mantle (MI), and adductor muscle (AMI) were calculated as follows:

$$\text{Organ index} = \frac{\text{Organ weight}}{\text{Total soft body weight}} \times 100$$

Tissue Biochemical Analyses

To obtain a crude extract of digestive glands and gonads (female and male portions separately), 0.3 g of tissue was homogenized in 3 mL of cold saline solution (NaCl 35 ppt). This extract was used for all biochemical analyses. Muscle and mantle samples were processed in a different way when determinations were made (explained later for each case) because of their toughness.

Soluble protein determination was done by the Bradford (1976) technique, using commercial chromogen reagent (Sigma-Aldrich, St. Louis, MO) and bovine albumin serum (Sigma-Aldrich) as standard solution. Samples were first digested during 2 h with 0.1 N NaOH at a 1:10 dilution. For mantle and muscle, 0.02 g of tissue were directly digested in 2 mL of 0.5 N NaOH during 24 h. Then, 1 mL of Bradford reactive solution was added to 10 μL of digested sample, and absorbance was read at 595 nm.

Total carbohydrates were determined by the anthrone method (Van Anel 1965) after protein precipitation with trichloroacetic acid (TCA). For gonads and digestive gland, the crude homogenate was diluted 1:2 with 20% TCA, whereas samples of muscle and mantle (0.5 g muscle or 0.9 g mantle) were directly homogenized in 5 mL of 10% TCA. In both cases, samples were centrifuged at 4000 rpm at 5°C for 10 min. Then, 1 mL of anthrone solution (0.1% dissolved in 76% sulfuric acid) was added to 0.1 mL of supernatant and incubated at 86°C for 2 to 10 min, depending on the concentration of carbohydrates in each tissue and sampling period. The reaction was stopped by cooling at 4°C in an ice bath, and absorbance was read at 620 nm. Total carbohydrates were quantified as glucosyl units, using a calibration curve of glucose treated in the same way as particular samples, especially for the incubation times.

Total lipids were determined by the sulfophosphovanillin method (Barnes & Blackstock 1973) using a commercial reactive and standard solutions (Merck). A volume of 0.5 mL of concentrated sulfuric acid was added to 50 μL of crude homogenate of gonads and digestive glands, incubated at 90°C for 10 min and immediately cooled at 4°C in an ice bath. Then, 20 μL were mixed with 200 μL sulfophosphovanillin solution in a microplate, incubated for 40 min, and absorbance read at 540 nm with a microplate reader (Biorad 550, Tokyo, Japan).

Acylglycerides were determined by a colorimetric-enzymatic kit (GOP-PAP, Merck). The crude homogenate of gonads and digestive glands was centrifuged at 4000 rpm at 5°C for 10 min. Then, 20 μL were mixed with 200 μL commercial chromogen solution in a microplate, incubated for 20 min, and absorbance read at 490 nm with a microplate reader (Labsystems, Uniscan II). Lipids and acylglycerides were not analyzed in the muscle and mantle due to the lack of sensitivity of these methods on those particular tissues, which have a very low lipid content.

All the biochemical techniques were previously standardized for each tissue. The results of each biochemical constituent were expressed in mg g^{-1} of dry weight of each organ tissue.

Statistical Analyses

One-way ANOVA, followed by mean comparisons *post hoc* Tukey test were made to assess significant differences in biochemical composition and indices among months. Pearson product moment correlations were used between IGS and DGI, AMI, and MI, and the different biochemical variables.

Because GSI, DGI, AMI, and MI values are reported as per-

centages, they were arcsine transformed (Zar 1996) to reduce the dependence of the sample variance on the mean and to normalize the data distribution. Data are reported as means. STATISTICA for Windows (version 6.0) was used for analyses. The level of significance was pre-set at $P < 0.05$.

RESULTS

Gonad Maturation Process

Monthly qualitative assessment of the reproductive condition is illustrated in Figure 1. In December 2000 and from January to March 2001, most lion's paw scallops (between 75% and 100%) were inactive (undifferentiated and spent stages). The development stage was present in low percentage in January (12.5%) and with high incidence starting in April and increasing gradually to July (60–90%). Ripe scallops were found from June to November. The highest proportion of ripe scallops was observed in August (100%). Small proportions of ripe and partially spawned scallops were found in February and March. A massive spawning period was observed from September to November (25–75% of the population).

Oocyte Diameters

The mean oocyte diameter (Fig. 2) showed significant differences among months (one-way ANOVA, $P < 0.01$) with a clear seasonality (Tukey *post hoc* test). The minimum mean oocyte diameter (23.5 μm) was observed in January, and the maximum (51 μm) was observed in August. In December and March, the scallops were spent or undifferentiated, and thus oocyte diameter was not estimated.

Organ Indices

Significant differences (one-way ANOVA, $P < 0.01$) were observed for GSI throughout the year (Fig. 3). GSI values were low from December to March (5.5–7.4%); they began to increase gradually starting in April, reaching their maximum in August (26.6%), which was significantly different from other months. From September to November, the GSI values fell to levels similar to December 2000.

Figure 2. *Nodipecten subnodosus*. Temporal variation in oocyte mean diameter. Data was analyzed by one-way ANOVA, followed by Tukey test. Means not sharing the same superscript are significantly different. Bars correspond to standard errors.

DGI values changed significantly (one-way ANOVA, $P < 0.01$) throughout the year (Fig. 3). The highest value was observed in January (7.96%) and the lowest in October (5.79%) with intermediate values for the other months. DGI showed a significant negative correlation with GSI ($r^2 = -0.43$, $P < 0.001$).

Values of AMI were more than 32% of total biomass from

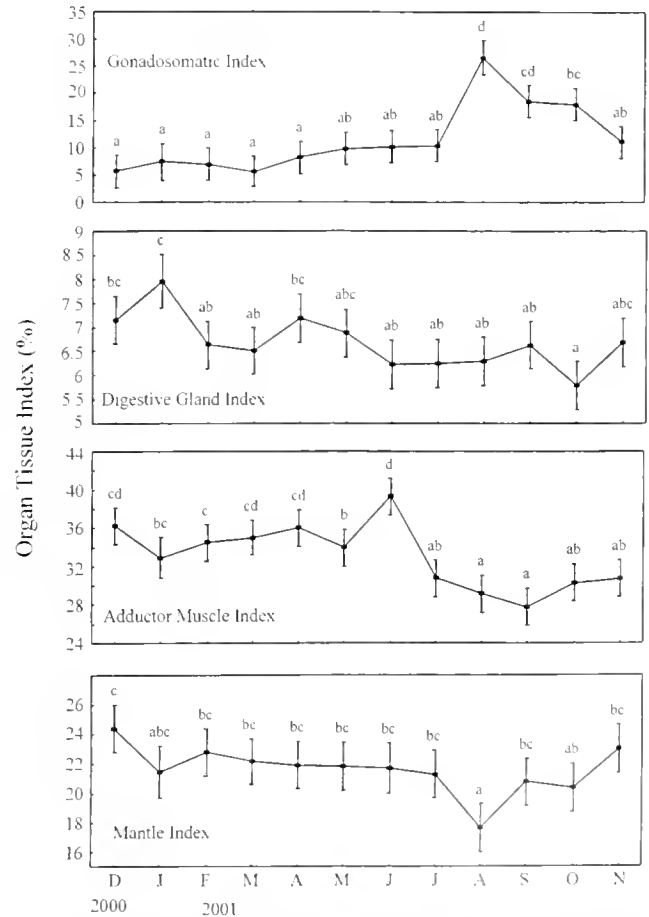

Figure 3. *Nodipecten subnodosus*. Temporal variation in the mean values of gonadosomatic index, digestive gland index, adductor muscle index, and mantle index. Data was analyzed by one-way ANOVA, followed by Tukey test. Means not sharing the same superscript are significantly different. Bars correspond to standard errors.

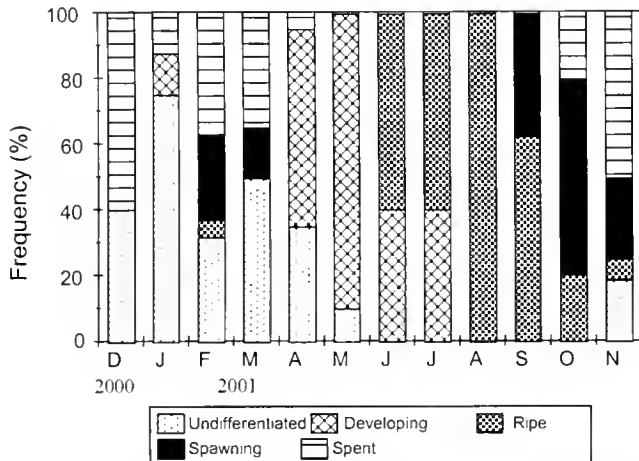

Figure 1. *Nodipecten subnodosus*. Monthly percent frequencies of the different gonad stages throughout the study period in Laguna Ojo de Liebre, B.C.S., Mexico. Male and female data were combined.

December 2000 to June 2001 and then significantly decreased (one-way ANOVA, $P < 0.01$) to values around 30% of biomass from July to November (Fig. 3). The AMI showed a significant negative correlation with GSI ($r^2 = -0.59$, $P < 0.001$).

Small, although significant (one-way ANOVA, $P < 0.01$) changes were observed for MI, which presented the highest value in December 2000 (24.2%) and the lowest in August 2001 (17.6%) (Fig. 3). The MI showed a significant negative correlation with GSI ($r^2 = -0.65$, $P < 0.001$).

Indicators of Quantity and Quality of the Food Available

Photosynthetic pigment concentration (chlorophyll *a* $\mu\text{g L}^{-1}$) and food index values in the Laguna Ojo de Liebre showed a similar variation throughout the year (Fig. 4). High chlorophyll *a* values (over $1 \mu\text{g L}^{-1}$) were observed in March and September–October in accordance with higher food index values (more than 11%). However, in September–October the higher values of chlorophyll *a* (1.19 and $1.2 \mu\text{g L}^{-1}$) were observed, but food index values were not the highest (under 12%).

Tissue Biochemical Composition

Protein

Protein was the major biochemical component of gonads. In the ovary portion, significantly lower values were observed from December to March. From April, the protein concentration increased gradually until significantly higher values were reached from June to October (Fig. 5). In the testis portion, a different pattern occurred (Fig. 5): protein increased gradually from January to April; then a decrease in protein concentration occurred from May to July, followed by a slight, though not significant, increase in August and September. Protein concentration in the ovary portion was significantly correlated to GSI ($r^2 = 0.55$, $P < 0.05$) but not in testis.

The digestive gland had a significantly lower concentration of proteins in April–May (Fig. 5). Higher values were observed in February and from June to August.

Protein levels in the adductor muscle were low from March to August (Fig. 5), whereas significantly higher values were observed from September to November.

In the mantle, the concentration of proteins decreased significantly from February to May (Fig. 5). Then, a significant increase was observed in July–August, followed by a significant decrease by September and then a further increase by November.

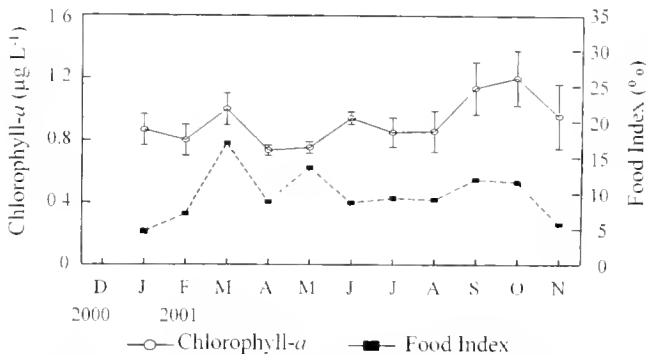

Figure 4. Temporal variation in chlorophyll *a* concentration and food index in the Laguna Ojo de Liebre, B.C.S., Mexico. Bars correspond to standard errors.

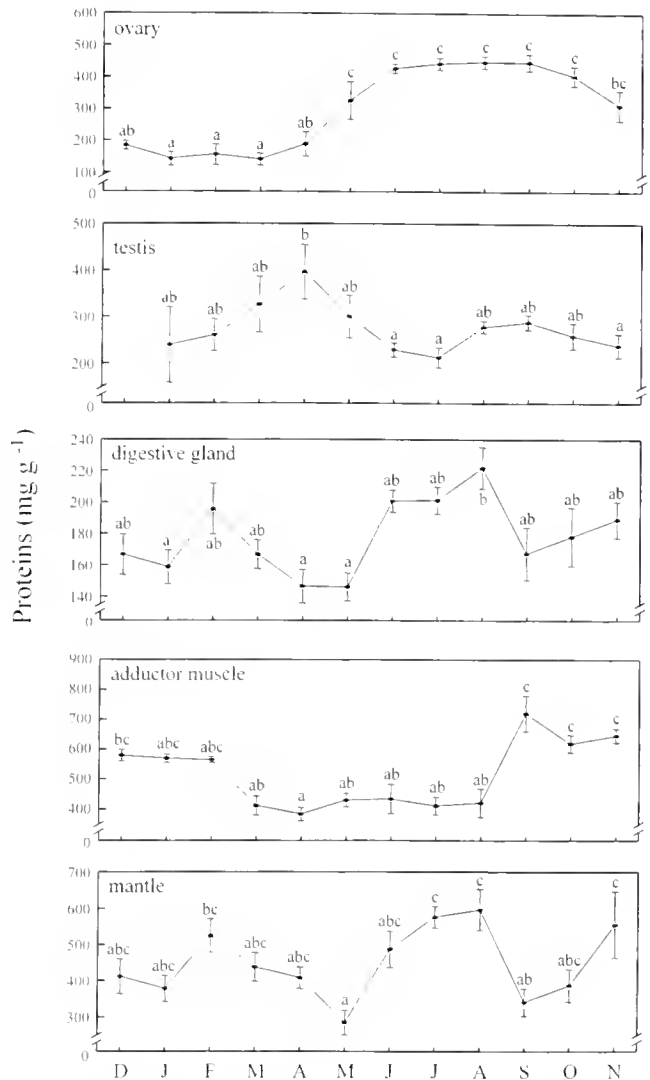

Figure 5. *Nodipeecten subnodosus*. Temporal variation in the content of protein in ovary, testis, digestive gland, adductor muscle, and mantle. Data was analyzed by one-way ANOVA, followed by Tukey test. Means not sharing the same superscript are significantly different. Bars correspond to standard errors.

Carbohydrates

In the ovary portion, the significantly lowest values were present from December to April. By May, carbohydrates concentration increased gradually until September, when the significantly highest values were observed. Then, the concentration of carbohydrates declined in October–November (Fig. 6). In the testis portion, a similar pattern was observed, although the significantly highest concentration of carbohydrates was present in August, and the decline occurred in September (Fig. 6). The GSI showed a significant correlation with carbohydrates of ovary ($r^2 = 0.6$, $P < 0.05$) and testis ($r^2 = 0.48$, $P < 0.05$) portions.

The levels of carbohydrates in digestive glands showed a tendency to increase progressively throughout the year, with significantly higher values in August–September (Fig. 6). Carbohydrates in digestive glands showed a significant correlation to GSI ($r^2 = 0.41$, $P < 0.05$).

The concentration of carbohydrates in adductor muscle in-

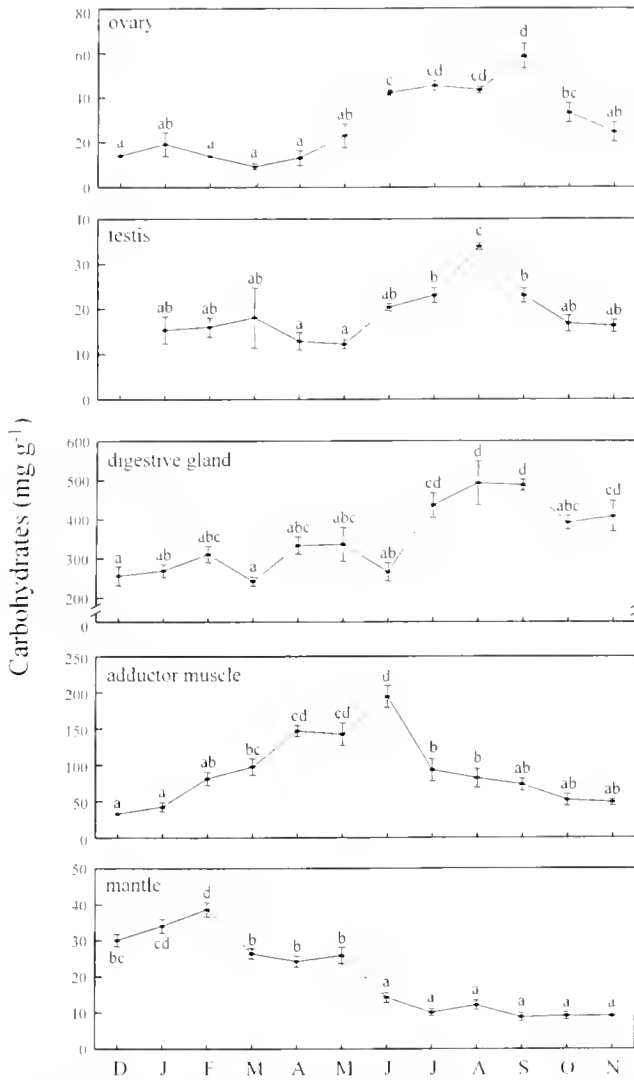

Figure 6. *Nodipecten subnodosus*. Temporal variation in the content of carbohydrates in ovary, testis, digestive gland, adductor muscle, and mantle. Data was analyzed by one-way ANOVA, followed by Tukey test. Means not sharing the same superscript are significantly different. Bars correspond to standard errors.

increased from December to June, when the significantly highest value was observed (Fig. 6). In July, a significant decrease was observed, and values continued to decrease until November.

The significantly highest concentrations of carbohydrates in mantle were observed from December to February (Fig. 6). Then, they decreased to intermediate levels from March to May and to the lowest values from June to November. Carbohydrates in mantle showed a significant negative correlation to GSI ($r^2 = -0.43, P < 0.05$).

Lipids

Lipids in the ovary portion showed a seasonal pattern. The lowest values were observed from December to April (Fig. 7). A significant increase was then observed from May, the highest values were attained from June to August, followed by a significant decrease from September to November. In the testis, lipids concentration did not change significantly throughout the year (Fig.

7). Concentration of lipids in the ovary portion showed a significant correlation to GSI ($r^2 = 0.47, P < 0.05$) but not in testis.

The concentration of lipids in digestive glands oscillated around high values from December to June with two peaks in February and May (Fig. 7). By July, lipids concentration fell significantly until November. Lipids showed a significant negative correlation to GSI ($r^2 = -0.38, P < 0.05$).

Acylglycerides

In the ovary portion, the lowest concentrations of acylglycerides were observed from December to March (Fig. 8). They increased from April, reaching significantly higher values from June to September, followed by a significant decrease in October and November. In the testis portion, acylglycerides levels showed a gradual but significant ($P < 0.01$) decrease from January to November (Fig. 8). Acylglycerides in ovaries were positively correlated ($r^2 = 0.51, P < 0.05$), whereas in testis they were negatively correlated ($r^2 = -0.33, P < 0.05$) to GSI.

The significantly highest concentrations of acylglycerides in digestive glands were observed from March to June (Fig. 8), whereas in the other months the values were significantly lower. Acylglycerides in digestive glands were negatively correlated to GSI ($r^2 = -0.41, P < 0.05$).

DISCUSSION

Gonad Maturation Process

Based on histologic data, the current study shows that the reproductive cycle of *Nodipecten subnodosus* may be divided into four periods: (1) period of quiescence from December to March (with a small reproductive activity in February–March), (2) period of initial reproductive activity from April to May, (3) period of

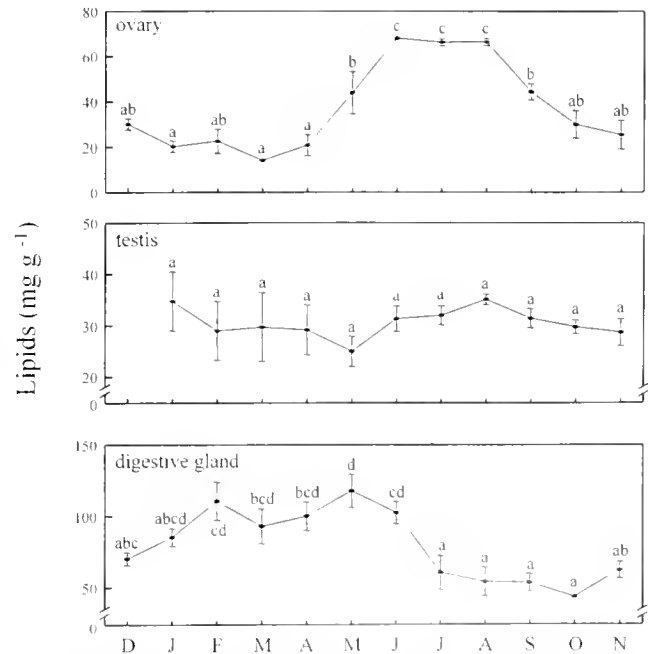

Figure 7. *Nodipecten subnodosus*. Temporal variation in the content of lipids in ovary, testis, and digestive gland. Data was analyzed by one-way ANOVA, followed by Tukey test. Means not sharing the same superscript are significantly different. Bars correspond to standard errors.

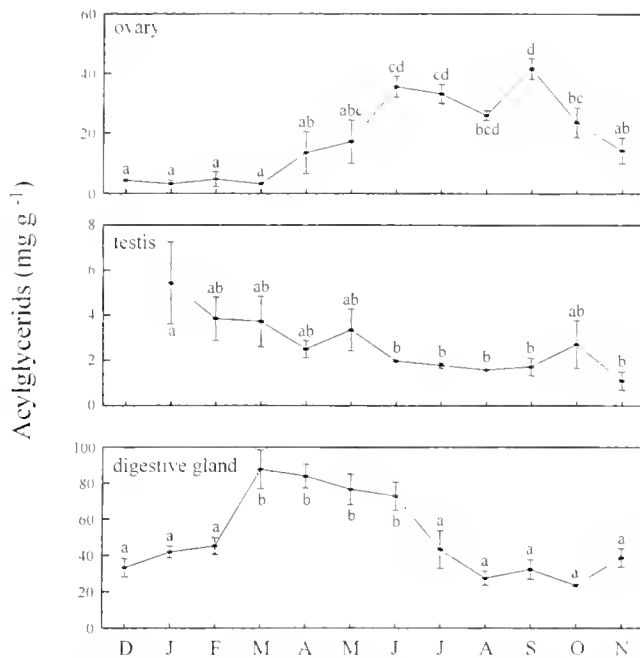

Figure 8. *Nodipecten subnodosus*. Temporal variation in the content of acylglycerids in ovary, testis, and digestive gland. Data was analyzed by one-way ANOVA, followed by Tukey test. Means not sharing the same superscript are significantly different. Bars correspond to standard errors.

maximum ripeness from June to September, and (4) period of spawning from September to November. This pattern is in accordance with previous studies of this species at the same locality (Reinecke-Reyes 1996) and at a southern locality (Racotta et al. 2003). However, in addition to the main spawning period, an earlier minor spawning is common in other species such as *Mya arenaria* (Brousseau 1987), *Pecten maximus*, *Pacopecten magellanicus*, and in the genus *Chlamys* (see Thompson 1977). Such a spawning was considered as facultative because it occurs only when environmental conditions are favorable (Brousseau 1987). In this sense, it is possible that *N. subnodosus* from Laguna Ojo de Liebre could begin a facultative spawning, as a slight reproductive activity was observed in February–March as indicated by the presence of some partially spawned scallops and by an increase in their oocyte diameter. However, in this period the IGS was low (<7%) as a consequence of the high proportion of spent (40%) and the presence of undifferentiated scallops (30%).

The positive correlations between all biochemical compounds analyzed in the ovary portion and the carbohydrates in the testis portion and GSI reflected their close relation to the reproductive activity. In relation to protein content in ovaries of pectinids, two patterns have been observed. Some studies showed an important accumulation of proteins in gonads during the ripening process (Barber & Blake 1981, Epp et al. 1988), whereas other studies reported that levels of protein in gonad tissue did not increase during gametogenesis (Thompson 1977, Couturier & Newkirk 1991, Pazos et al. 1996, Racotta et al. 1998, Ruíz-Verdugo et al. 2001, Racotta et al. 2003). However, these patterns probably are not a species-specific strategy, because *N. subnodosus* shows both patterns depending on the locality (Racotta et al. 2003 vs. current study). In the testis portion, a different variation in the protein content was found, as it decreased in accordance with the ripening

process in this study. In other functional hermaphrodite pectinids, contrasting results have been obtained. In *P. maximus*, the protein contents of the testis and ovary portions were nearly identical throughout the study (Lubet et al. 1987), whereas in *Argopecten purpuratus*, the protein level was higher in the female than in the male portion of the gonad in mature organisms (Martínez 1991). A possible explanation of our results is that proteins were transferred from the testis portion to the ovary portion during ripening and accumulated as yolk. Further work is necessary in functional hermaphroditic bivalves to test this hypothesis.

Despite that previous studies in pectinids have not reported an increase in the levels of carbohydrates in gonads associated with reproductive activity (Barber & Blake 1981, Couturier & Newkirk 1991, Martínez 1991, Pazos et al. 1996), our results indicated a significant increase during the entire maturation process and a decrease in the spawning period. It has been suggested that the accumulated carbohydrates in developing gonads can be used as an immediate available energy source for lipid synthesis or spawning (Racotta et al. 1998, Ruíz-Verdugo et al. 2001, Racotta et al. 2003) and also as precursors for lipid synthesis during the formation of gametes, which is known to occur in mollusks (Gabbott 1975, Lubet 1976, Barber & Blake 1985). Our results suggest that in *N. subnodosus*, the carbohydrates of testis could be used as an energy source for sperm motility.

The accumulation of total lipids and acylglycerides that we found in the ovary portion is an important and well documented process occurring during ripening in scallops (Barber & Blake 1991, Couturier & Newkirk 1991, Martínez 1991, Pazos et al. 1997, Racotta et al. 2003). These reserves are stored in ripening eggs and may subsequently be used by the larvae as an energy source during the first life stages of growth and metamorphosis (Holland 1978, Barber & Blake 1991, Couturier & Newkirk 1991). In contrast, in our results, acylglycerides levels in testis decreased significantly in parallel with the ripening process, and their concentration was negatively correlated to GSI. As for proteins, acylglycerides could be transferred from the testis portion to the ovary portion during the ripening process for the accumulation in gametes as yolk. In *P. magellanicus* (Thompson 1977, Robinson et al. 1981, Couturier & Newkirk 1991), *Chlamys septemradiata* (Ansell 1974), and *A. purpuratus* (Martínez 1991), the ovarian lipid content was higher than in the testis portion in ripe organisms.

Energy and Nutrient Supply for Gametogenesis

It is known that the mollusk digestive gland is responsible for nutrient storage and transfer of assimilated food to body tissues, and that the initiation of the oocyte growth phase is dependent on the accumulation and transfer of nutrient reserves from the digestive gland to the gonad (Sastry & Blake 1971, Gabbott & Bayne 1973, Vassallo 1973, Barber & Blake 1983, Pazos et al. 1997, Lodeiros et al. 2001). The variations of lipid, acylglyceride, and protein concentrations during gonad ripening observed in this study are in accordance with this transfer of energy and nutrients to the gonad for ripening in *N. subnodosus*. The rapid decrease in protein content between March and May (phase of early oocyte development) indicates that this substrate could be used for structural purposes during oocyte differentiation. On the other hand, the decline of lipids and acylglycerides between July and October indicated that they are used for yolk formation. Carbohydrates tend to increase slightly in the digestive gland, despite the development of gonads, thus suggesting that this organ did not transfer carbo-

hydrates to the gonad. In contrast to the apparent mobilization of proteins and lipids, Racotta et al. (2003) did not obtain any changes of these substrates in the digestive gland of *N. subnodosus* in Bahía Magdalena during gonad development.

The storage and mobilization of metabolic substrates from adductor muscle to the gonad during gametogenesis has been reported in bivalves, particularly for several pectinids such as *A. irradians* (Barber & Blake 1981, Epp et al. 1988), *Chlamys opercularis* (Taylor & Venn 1979), *P. maximus* (Comely 1974), *A. ventricosus* (Racotta et al. 1998), *A. purpuratus* (Martínez 1991), and *N. subnodosus* (Racotta et al. 2003). The depletion of proteins observed in adductor muscle from March to August suggests that lion's paw scallops use this reserve for supporting the whole process of gametogenesis. These results are in agreement with those reported for this (Racotta et al. 2003) and other pectinids, including *P. maximus* (Comely 1974), *C. opercularis* (Taylor & Venn 1979), *A. irradians* (Epp et al. 1988), *P. magellanicus* (Couturier & Newkirk 1991, Faveris & Lubet 1991), and *A. ventricosus* (Racotta et al. 1998). However, these results contrast with those of Barber and Blake (1981, 1985) and Brokordt et al. (2000), who suggest that protein reserves are used only to meet the cost of maintenance during final ripening and spawning.

In contrast, muscle carbohydrates increased from February to June, when oocytes started growing, but concentration decreased significantly during the final ripening phase (July to October) and during spawning (September to November). From the above, it is evident that *N. subnodosus* in Laguna Ojo de Liebre used carbohydrates stored in muscle to meet the final ripening and spawning needs.

The relative importance of the role of adductor muscle protein and carbohydrate reserves in supporting energy demands during reproduction in scallops is controversial. In some pectinids, the adductor muscle protein appears as the major energy reserve, which supplies the demand during gametogenesis (Barber & Blake 1985, Epp et al. 1988, Couturier & Newkirk 1991, Faveris & Lubet 1991, Pazos et al. 1997, Racotta et al. 1998, Racotta et al. 2003). In other species, the energy demands during gametogenesis are mainly supported by adductor muscle glycogen (Comely 1974, Taylor & Venn 1979, Barber & Blake 1981, Robinson et al. 1981).

The mantle tissue as a storage organ and its relation to gametogenesis has been observed in mussels (Gabbott 1975, Bayne et al. 1982, Mathieu & Lubet 1993) and scallops (Lodeiros et al. 2001). In the current study, a decrease in mantle proteins during early gonad development (March–May), as well as a further decrease in mantle carbohydrates during final ripening and spawning (June–November), may be considered as evidence that the lion's paw scallops store nutrients in the mantle to be transferred to the gonad during ripening.

The seasonal changes of biochemical composition in several somatic tissues of the lion's paw scallop *N. subnodosus* in this locality indicate a clear energy storage and use cycle strongly related to reproductive activity, as is common in other pectinids (Gabbott 1975, Barber & Blake 1991, Mathieu & Lubet 1993). This is further supported by significant negative correlations between several biochemical components in somatic tissues and GSI, as well as by the significant negative correlations of all somatic organ indices with GSI. The relation between organ indices and gonad development have been reported for scallops as an indicator of energy storage and use patterns (Barber & Blake 1981, Barber & Blake 1983, Villalejo-Fuerte & Ceballos-Vázquez 1996, Barrios 1997).

The current study shows that gametogenesis in *N. subnodosus*, at the locality of Laguna Ojo de Liebre, relies on previously stored reserves and thus behaves as a conservative species (Bayne 1976). In contrast, the results obtained by Racotta et al. (2003) for the same species, but at a southern locality (Bahía Magdalena), indicate that reproductive activity depends minimally on previously stored reserves, showing an opportunistic behavior (Bayne 1976). It is known that both strategies can be adopted by the same species to support gametogenesis, depending on food availability on a specific locality, which in turn depends on environmental variables that influence primary productivity (Barber & Blake 1991, Thompson & McDonald 1991, Luna-Gonzalez et al. 2000).

In this sense, Bahía Magdalena is considered a eutrophic lagoon with high primary productivity (Gómez-Gutiérrez et al. 2001), whereas our results show that Laguna Ojo de Liebre has a low food availability (maximum $1.2 \mu\text{g L}^{-1}$ chlorophyll *a*) year round, which agrees with previous works (Millan et al. 1987, Delgadillo-Hinojosa et al. 2002). Additionally, the food index (FI) values observed in our work (maximum 17%) can be considered as indicative of a low nutritional quality of the food available to suspension-feeders. Sites considered with a nutritionally dilute environment had FI values between 8% and 11% (Soniati et al. 1984, Luna-Gonzalez et al. 2000), whereas sites with a nutritionally rich environment had FI values as high as 55% (Navarro & Thompson 1995).

This could explain the contrasting results between our study and the previous work of Racotta et al. (2003). Then, the reproductive strategy (opportunistic vs. conservative) of *N. subnodosus* could be considered as an adaptation to food availability in a particular environment. A similar switch between both strategies was reported for *A. ventricosus* (Luna-Gonzalez et al. 2000) and *P. maximus* (Pazos et al. 1997), which use the available food in the environment, more than reserves, for gonadal ripening when the food is abundant, but they use the muscle reserves when the food abundance is poor.

Finally, changes in temperature, salinity, or photoperiod have been considered as physical environmental variables inducing spawning of bivalves (Mann 1979, Lubet et al. 1987). Park et al. (2001) mentioned that food availability also may have an effect on the initiation of spawning, and Starr et al. (1990) demonstrated that phytoplankton levels during blooms should be sufficient to induce spawning in *Strongylocentrotus droebachiensis* and *Mytilus edulis*. For other scallops, it has been suggested that spawning may be triggered by changes in temperature (Luna-Gonzalez et al. 2000) or phytoplankton blooms (Arsenault & Himmelman 1998). In *N. subnodosus* from Laguna Ojo de Liebre, the start of spawning coincides with the higher concentrations of chlorophyll *a*; then it is possible that the spawning of *N. subnodosus* was triggered by the higher concentrations of chlorophyll *a*, which, additionally, may ensure the food supply for larvae (Newell et al. 1982).

ABSTRACT Reproduction in scallops, as in many broadcast-spawning invertebrates, involves the production of a gonad that can become the largest tissue in the body. Gonad maturation leads to mobilization of macromolecular reserves from somatic tissues in many scallops. Because ovaries typically contain higher energetic contents than testes, we examined whether the energetic investment in gonad production and spawning and the impact on somatic tissues was greater in female than male Iceland scallops, *Chlamys islandica*. In males and females, maturation led to accumulation of carbohydrate and protein in the gonads, whereas lipids only accumulated in the ovary. In both sexes, the increase in gonad mass was accompanied by decrease of carbohydrate in muscle and the remaining tissues, but testes maturation was also paralleled by loss of carbohydrates and lipids from the digestive gland. Although spawning led to a greater energy loss in the female than in the male gonads (73 vs. 49 kJ in gonad energy content), less mobilization of somatic energy was observed during gametogenesis and spawning in females than males (14.5 kJ vs. 36.7). Most of the energy requirements for maturation and spawning in females must have been covered by feeding, whereas somatic reserve mobilization could have covered most of these costs in males. As in most scallop species, lipids account for a major part of the ovarian energy content. Direct deposition of dietary lipids in the eggs could minimize the impact on somatic tissues of female scallops. The costs of protein synthesis during testes maturation could decrease the aerobic scope available for feeding by males. In light of our previous demonstration of the impact of gonad maturation in *C. islandica* on recuperation from exhaustive exercise, our results suggest that the survival of males may be decreased more by their reproductive investment than that of females. The bioenergetic strategies of female scallops seem to favor survival and hence future reproduction more than those of male scallops.

KEY WORDS: biochemical reserves, *Chlamys islandica*, reproduction, reproductive cost, scallops, sex differences

INTRODUCTION

Intraspecific variation in how the reproductive cycle of scallops affects the mass and biochemical composition of body components has been attributed to the timing of gonad proliferation (Shafee 1981), to the habitat of the populations under study (eg. depth, protected or exposed) (MacDonald & Thompson 1986, Bricelj et al. 1987, and Epp et al. 1988), to the size or age group examined (Epp et al. 1988 and Martínez 1991), to the abundance and quality of the food supply, and to temperature (Shafee 1981, MacDonald & Thompson 1986, and Martínez et al. 2000). However, little is known about differences in reproductive investment between male and female scallops. In hermaphroditic scallops, the question of the relative investment in the male and female portion of the gonad is intriguing (Faveris & Lubet 1991), but marked qualitative and quantitative differences in reproductive investment of males and females are likely in species in which sexes are separate.

The cost of reproduction is typically believed to be higher in females than in males, given the large size of the egg relative to the sperm. Nuptial gifts, territorial defense, and paternal care of offspring can make the cost of reproduction higher for males than females. However, in broadcast spawning scallops, such behavioral considerations are unlikely to modify the cost of reproduction. The fact that the gonad can be the largest organ in scallops clearly indicates high investment in reproduction (Barber & Blake 1991), but whether the impact of this investment varies between males and females is an open question. The little that is published about sex differences in reproductive investment indicates that male and female scallops can differ in the size of the gonad (Couturier &

Newkirk 1991) and although the mature ovary and testis have similar protein contents, the ovary is richer in lipid (Couturier & Newkirk 1991 and Brokordt et al. 2000a). Various studies have examined reproductive investment in scallops, but most present pooled data for males and females. If investment in a given reproductive cycle decreases individual survival, it would reduce future reproductive success and thereby decrease fitness. Thus, reproductive investment represents a compromise between current and future reproduction. These compromises will differ between males and females if their equations linking reproductive investment with reproductive success and individual survival differ.

Mobilization of somatic reserves in support of reproduction should vary as a function of reproductive investment and of food availability. Mobilization of glycogen from the adductor muscle in support of gametogenesis and spawning occurs even when food availability is high (see Barber & Blake 1991 for review). In the Iceland scallop, *C. islandica*, and in the tropical scallop, *Euvola ziczac*, glycogen mobilization during gonad growth is accompanied by decreases in muscle activities of enzymes in energy metabolism and in the capacity to recover from exhaustive exercise (Brokordt et al. 2000a and Brokordt et al. 2000b). In *Argopecten purpuratus*, the decrease of muscle glycogen during gonad maturation also coincided with a marked decrease in escape capacities (clapping and recovery, K. Brokordt, unpubl. data). This suggests that mobilization of somatic reserves in scallops may decrease individual survival during attack by predators. In the black scallop, *Chlamys varia*, gametogenesis and spawning occur during periods of high and low food availability (spring and autumn, respectively), and only the autumn reproduction leads to extensive mobilization of protein, lipid, and carbohydrate from somatic tissues (Shafee 1981). In a comparison of two successive reproductive cycles in *E. ziczac*, recuperation from exhaustion was more im-

*Corresponding author. E-mail address: Helga.Guderley@bio.ulaval.ca.

paired in the first cycle in which reproductive investment was high while food availability was low. Muscle protein levels only declined during the first cycle, whereas muscle glycogen and enzyme levels declined during both cycles (Brokordt et al. 2000b). In these scallop species, gametogenesis and spawning consistently lead to depletion of muscle glycogen, but their impact on other somatic reserves and recuperation from exhaustion (in the case of *E. ziczac*) varies according to food availability and the extent of reproductive investment.

In this study we examined whether male and female Iceland scallops, *C. islandica*, differ in their reproductive investment and somatic reserve mobilization during a reproductive cycle. The greater lipid levels in mature ovaries (Brokordt et al. 2000a) suggest that females invest more energy in reproduction than males. However, as the synthesis of lipids may be less costly than that of proteins, the cost of spermatogenesis may exceed that of oogenesis. In the northern Gulf of St. Lawrence, a natural population of *C. islandica* shows marked and rapid gonad maturation during the spring increase in phytoplankton followed by a precipitous and synchronous spawning (Arsenault & Himmelman 1998). We sampled sexually mature males and females in a narrow size range (shell height = 79–81 mm) while their gonads were immature (May 30), mature (July 20) and after spawning (August 14). The mass and biochemical composition of the body components were measured and converted to energetic units using calorific coefficients to assess whether males and females differed in their reproductive investment and in its impact on somatic reserves. We measured carbohydrate, protein and lipid levels in the gonads, digestive gland, remaining tissues, (mantle, gill, foot, etc) and protein and glycogen levels in the adductor muscle. Because lipid levels in the adductor muscle are below 5% of dry mass (Couturier & Newkirk 1991) and typically change little throughout the reproductive cycle, they were not measured.

MATERIALS AND METHODS

Sampling, Animals, and Tissue Analyses

We studied the population of *Chlamys islandica* in the Mingan Islands (50°14'N, 63°36'W) in the northern Gulf of St. Lawrence, eastern Canada. Adult scallops (height 79–81 mm), 15 females and 15 males, were collected by SCUBA diving at 37 m in depth on May 30, July 20, and August 14, 2000. For both females and males, these sampling dates corresponded to when the gonads were immature, completely mature, and spawned. At each sampling period, we determined the shell height and wet and dry masses (oven-dried for 48 h at 80°C) of four body components: gonad, muscle, digestive gland, and the remaining tissues (mantle tissue, gills, excretory organ, foot, etc., henceforth referred to as remaining tissues). Tissues were frozen at -20°C, transported frozen to Université Laval, and then stored at -70°C until biochemical analysis.

Biochemical and Energetic Analyses

We determined the carbohydrate content in the female and male gonads, digestive gland, and remaining tissues using the phenol-sulfuric acid method of Dubois et al. (1956), as modified by Martínez (1991), with mussel glycogen as the standard. For the adductor muscle we determined the glycogen content by enzymatic hydrolysis with amyloglucosidase as described by Keppler and Decker (1974). The protein content in gonads, muscle, digestive

gland, and remaining tissues was determined using the bicinchoninic acid method of Smith et al. (1985), with bovine serum albumin as the standard. We determined the lipid content of all tissues (except for muscle) by extraction with chloroform-methanol according to Folch et al. (1957) and colorimetric determination with phosphovanillin, using tripalmitin as the standard (Postma & Stroes 1968).

Energy losses and gains by each body component during gonad maturation and spawning were estimated using the following energy conversion factors: carbohydrate = 17.2 kJ g⁻¹, protein = 20.1 kJ g⁻¹, lipid = 35.3 kJ g⁻¹ (Brody 1945 and Beukema & De Bruin 1979). These factors were applied to mean values of each biochemical component measured during the reproductive cycle.

We present the tissue mass and biochemical components on a per animal basis, (ie, as absolute composition). This was possible as we sampled animals over a narrow size range. Other forms of presentation may confound interpretation of results (Couturier & Newkirk 1991) (ie, relative composition involves reciprocal relationships between the components and this may lead to misinterpretation of the underlying biologic phenomena).

Statistical Analyses

For all comparisons between sampling dates for each sex we analyzed the data using one-way ANOVAs to test the null hypotheses of no differences between reproductive stages (Sokal & Rohlf 1981). Comparisons between sexes at specific sampling dates used *t*-tests. Normality was tested using a Shapiro-Wilk's test (SAS 1991) and homogeneity of variances using a Levene test (Snedecor & Cochran 1989). LS means multiple pairwise comparisons were used to test *a posteriori* for specific differences when the ANOVAs indicated significant ($P \leq 0.05$) differences (SAS 1991).

RESULTS

Masses of Body Components

During the period from May 30 to August 14, 2000, marked changes in the wet and dry mass of gonad and somatic components were apparent, particularly in male scallops (Fig. 1). These changes occurred despite a lack of difference in shell height of the males sampled on these dates ($P = 0.68$). The wet and dry mass of the testes and ovary increased markedly between May 30 and July 20 and decreased precipitously by August 14, indicating gonad maturation and spawning, respectively. Testis dry mass was significantly ($P = 0.018$) larger than ovarian dry mass on May 30. This suggests that gonad maturation was advanced in males relative to females. Such a pattern was observed for this population of *C. islandica* during the reproductive seasons of 1990 and 1991 (D. Arsenault, personal communication). At maturity, the wet mass of the ovaries was greater than that of the testes ($P = 0.0005$), although dry masses were similar ($P = 0.53$), suggesting that ovaries are more hydrated when fully mature. In females, during maturation and spawning most body components (wet and dry masses) remained stable ($P > 0.05$), with the exception that the dry mass of the remaining tissues (mainly mantle and gills) was lowest after maturation and increased after spawning ($P < 0.05$) (see Fig. 1). In males, during gonad maturation and spawning, the digestive gland mass decreased steadily, attaining its lowest value after spawning ($P < 0.05$). Adductor muscle dry mass dropped ($P < 0.05$) during testis maturation and recovered slightly after spawn-

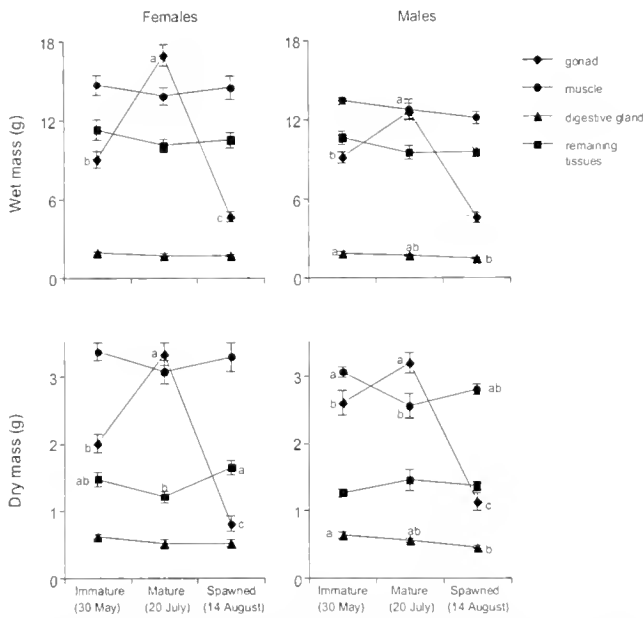

Figure 1. Total wet and dry masses (g) of the gonad, muscle, digestive gland and remaining tissues (mainly mantle) of females and males *C. islandica*, sampled at three different dates (May 30, July 20, and August 14, 2000) corresponding to when gonads were immature, mature and spawned. Values represent means \pm SE ($n = 15$). Means sharing the same letters were not significantly different ($P < 0.05$) as determined by LS means multiple comparisons.

ing, whereas the mass of the remaining tissues stayed constant (see Fig. 1).

No sex differences in the mass of the adductor muscle, digestive gland, and remaining tissues were observed ($P > 0.05$) before and after gonad maturation. However, after spawning, the wet and dry masses of the adductor muscle, digestive gland, and remaining tissues were lower ($P < 0.05$) in males than in females. This difference was not significant for the digestive gland when measured as dry mass ($P = 0.059$).

Biochemical Components

During gonad maturation, the absolute contents of carbohydrate and protein in ovary and testis increased markedly. Lipid levels only increased in the ovary (Fig. 2). In parallel, glycogen in the adductor muscle decreased by 160 and 185 mg in females and males, respectively, carbohydrates in the remaining tissues dropped by 70 and 66 mg in females and males respectively, and male scallops showed a 15 mg decrease of digestive gland carbohydrates. In contrast, the carbohydrate content of the female digestive gland increased by 19 mg during maturation (see Fig. 2). During gonad maturation, protein contents remained constant in all somatic tissues, and somatic lipids only decreased in the male digestive gland (467 mg) (see Fig. 2).

After spawning, all biochemical components of the ovary and testis dropped to their lowest levels (see Fig. 2). In female and male scallops, muscle carbohydrate remained low, however carbohydrate in the remaining tissues returned to pre-maturation levels. Protein levels in the digestive gland decreased by 80 mg with spawning of male scallops, whereas lipid levels decreased by 288 and 400 mg in females and males, respectively (see Fig. 2).

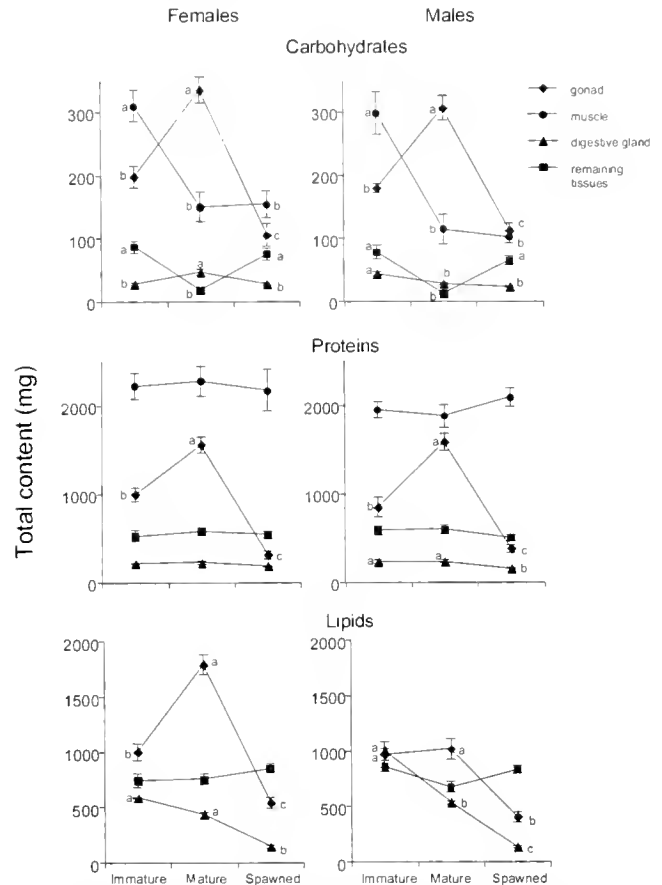

Figure 2. Total content (mg) of carbohydrates, proteins and lipids in the different body components (gonad, muscle, digestive gland and remaining tissues) of females and males *C. islandica*, when they were immature, mature and spawned. Values represent means \pm SE ($n = 15$). Means sharing the same letters were not significantly different ($P < 0.05$) as determined by LS means multiple comparisons.

Energetic Changes During Maturation

During the period of ovary maturation we studied, female somatic components lost a total of 4 kJ (taking only statistically significant variations into account), while the ovary gained 41.5 kJ (Table 1). Thus, somatic tissues contributed only 10% of the energetic gain of ovaries. Adductor muscle provided 70% and the remaining tissues 30% of this energy. Only carbohydrate was responsible for the energetic loss of somatic tissues in females. If the decrease in lipids in the digestive gland, even though it was not significant, is included in this calculation, 25% of the ovarian energy gain was explained.

During the period of testis maturation we studied, somatic tissues lost a total of 21 kJ, while testis gained 17 kJ (Table 2). Therefore, the energetic gain of the testis was completely supported by somatic tissues. Digestive gland accounted for 80%, adductor muscle 15%, and the remaining tissues 5% of the total caloric loss in the somatic tissues during testes maturation. In the digestive gland 99% of the energetic reduction was caused by lipid loss and 1% to carbohydrate loss. The total caloric loss in the adductor muscle and remaining tissues was caused by carbohydrate. The remaining tissues also showed a marked reduction of lipid but, as in the digestive gland, this was not statistically significant.

(n.s. = not significantly different, $P < 0.05$, n.e. = not evaluated)

During the period of gonad maturation we studied, somatic proteins made no energetic contribution in males or females. In males, lipids represented 78% and carbohydrates 22% of somatic energy loss. In females, only carbohydrate reserves showed statistically significant changes. Although the energetic gain in the ovary was more than 2-fold that of the testis, the increments in protein and carbohydrate were similar in both gonads (see Tables 1 and 2). The difference in energy gain reflected the marked increase in ovarian lipids, whereas the change in testicular lipids was not significant.

Energetic Changes With Spawning

During spawning, the ovary lost 73 kJ and testis 49 kJ, confirming the greater energetic investment in egg production. The

remaining tissues in females and males increased their caloric content, mainly because of the recovery of initial carbohydrate levels (see Tables 1 and 2). Adductor muscle energy contents did not change. On the other hand, the energy content of the digestive gland dropped to its lowest level in females and males, mainly caused by lipid loss. Thus, the somatic contribution to energy requirements during spawning came from digestive gland lipids in female and male *C. islandica*. The total energetic decrease during spawning was 83.5 kJ in females and 65.2 kJ in males.

DISCUSSION

In the Mingan Islands, gonad maturation and spawning of *C. islandica* was accompanied by changes in body mass and biochemical components that differed markedly between males and

females. Although spawning led to a considerably greater energy loss in female than in male gonads (73 vs. 49 kJ in gonad energy content), less mobilization of somatic energy was observed during gonad maturation and spawning in females than males (4 vs. 21 kJ during maturation and 10.5 vs. 15.7 kJ with spawning). The sex difference in investment during maturation (41.5 kJ vs. 17 kJ) was accentuated by the fact that the testes were larger than the ovaries at the start of our study, due to an advanced gametogenesis in males (Arsenault & Himmelman 1998). However, despite their greater reproductive investment, female scallops showed less somatic energy mobilization. Most of the energy requirements for ovarian maturation must have been covered by feeding, whereas somatic reserve mobilization could have covered the costs of maturation in males.

The sex differences in the changes of somatic reserves during gonad production and spawning were opposite those we predicted. What factors could explain the observation that female scallops can support the production of energetically expensive ovarian tissue by feeding, whereas males break down somatic tissues? Because the male and female scallops were sampled in the same habitat, food availability did not differ. If sperm production increases metabolic rate more than egg production, then the availability of aerobic power for food assimilation could be reduced thereby limiting feeding. Because the metabolic rate of mature male *C. islandica* is higher than that of mature females (Vahl & Sundet 1985), the aerobic scope available for feeding and assimilation could be lower in males than females. Protein levels increased more in the testes than in the ovaries during maturation, whereas lipids increased only in ovaries (see Fig. 2). *De novo* protein synthesis for sperm production is likely to be more costly than lipid deposition in the yolk. Protein synthesis requires activation of amino acids during their incorporation into nascent polypeptides and may require production of the appropriate amino acids. Because dietary fatty acids can be directly esterified into triglycerides and phospholipids, the energetic cost of lipid absorption and deposition is lower than the calorific value of the lipids. The close morphologic association between the digestive gland and the gonad could facilitate the direct transfer of lipids from food to gametes. Whereas these mechanistic explanations for the sex difference in breakdown of somatic reserves are speculative, our results suggest that male survival may be decreased by their reproductive investment whereas female scallops maintain greater survival and hence future reproduction.

In female *C. islandica*, the energetic gain by the ovary (41.5 kJ) during its growth was ~10 fold greater than the energetic loss in somatic tissues (muscle + digestive gland + "remaining tissues" = 4.0 kJ) (see Table 1). Even if the lipid change in the digestive gland (not significant) is taken into account, energy gain by the gonad was 4-fold the loss of somatic tissues. Therefore, because energy loss by somatic tissues must have accounted for only a small fraction of ovarian growth, external food supplies covered the remainder of this growth. The fact that, in *C. islandica* from the Mingan Islands, most ovarian maturation occurs during the spring-summer peaks of food concentration (Spence & Steven 1974, Arsenault & Himmelman 1998, and Brokordt et al. 2000a) suggests this is feasible. This is not what occurs in *Pecten maximus*, in which gonad growth takes place during the winter, and in which the energy loss by the adductor muscle was 23% larger than energy gain by the gonad (no differences were made between sexes because *P. maximus* is a hermaphrodite) (Faveris & Lubet 1991). Thus adductor muscle reserves in *P. maximus* support not only

gonad growth but also maintenance requirements, maybe because of low food availability during winter. These observations in *P. maximus* are similar to our results for male *C. islandica*. In summary, during gonad maturation, female *C. islandica* only mobilized carbohydrate reserves, mainly from muscle but also from the remaining tissues. Males mobilized both lipids (from the digestive gland) and carbohydrates (from all somatic tissues, but mainly from muscle), but lipid mobilization was more important in terms of amount (mg) and energy content (kJ). Therefore, the energetic support of ovarian maturation was carbohydrate based whereas testis maturation was primarily lipid based. During spawning, energetic demands in females and males are mainly supported by lipids from the digestive gland, but again males made a bigger somatic effort, losing 15.7 kJ versus a loss of 10.5 kJ in females (see Tables 1 and 2). Therefore, somatic energy loss during gonad growth and spawning was 2.5-fold greater in male than in female *C. islandica* (36.7 kJ and 14.5 kJ, respectively). Again this suggests that reproduction would reduce survival more in male than female scallops.

We analyzed the changes of biochemical components in the body tissues during gonad maturation and spawning in 13 species of scallops (Table 3) to compare with our results for *C. islandica* and to seek a common pattern for scallops. This compilation included species from different geographic zones and different degrees of biochemical analysis (not all of them included all somatic tissues or biochemical substrates). Most of the scallop species studied (11 of 13), used one or more energy reserves during gonad maturation. The two exceptions were *Chlamys septemradiata* from the Clyde Sea, England (Ansell 1974), and *Nodi Pecten subnodosus* from Bahía Magdalena, Mexico (Racotta et al. 2001), species that increased biochemical components in all somatic tissues during gonad maturation. In these species, gonadal growth was supported directly and only by feeding. Other partial exceptions are some species or populations that have more than one reproduction or partial spawning per year, like *P. maximus* and *Aequi Pecten opercularis* from Ría de Arousa (Galicia, Spain) (Pazos et al. 1997 and Román et al. 2003) and *Chlamys varia* (Shafee 1981), in which spring gametogenesis and spawning are usually supported by external food supplies, which are abundant during this season. In contrast, autumn or winter reproduction in all the three species is supported by somatic tissue reserves. As a general pattern, and as found in female *C. islandica*, most species use carbohydrates (9 of 11), mainly from muscle and (8 of 9) as an energy substrate for supporting gonad maturation. Lipid and protein reserves were equally used during gonad growth (6 of 11), lipids coming mainly from the digestive gland (4), and proteins from adductor muscle (4). Reliance on muscle and mantle proteins is particularly pronounced in the semelparous *A. irradians concentricus* (Barber & Blake 1981) and *A. irradians irradians* (Epp et al. 1988). Thus, the literature shows that adductor muscle is the most important storage tissue providing energy substrates for gonad maturation in scallops, but that the extent of mobilization and the reserve used depends on food availability during maturation and the reproductive strategy (single vs. multiple spawners).

Of the 13 studies we analyzed, 10 evaluated the changes of biochemical components in body tissues during spawning (see Table 3). In some species, spawning is accompanied by recuperation of energy substrates depleted during gonad growth. This occurred in *Pecten maximus* from the Baie de Seine, France (Faveris & Lubet 1991), in *C. varia* from Bretagne, France (Shafee 1981), *Argopecten irradians irradians* from New York, United States

(Epp et al. 1988), and for mantle carbohydrates in male and female *C. islandica* (present study). However, most scallop species continue depleting the same biochemical reserves that were used during gonad maturation, or used reserves that were not used during gonad growth, to support energy demands during spawning. This was seen in *C. islandica*, *C. septemradiata*, *Placopecten magellanicus* from Nova Scotia, Canada (Couturier & Newkirk 1991), *A. irradians concentricus* from the Gulf of Mexico, United States (Barber & Blake 1981), *E. ziczac* from the Golfo de Cariaco,

Venezuela (Brokordt et al. 2000b), *A. purpuratus* from Coquimbo, Chile (Martínez 1991 and Martínez et al. 2000) and *Lyropecten (Nodipecten) nodosus* from the Golfo de Cariaco, Venezuela (Lodeiros et al. 2001). As during gonad maturation, adductor muscle reserves were most frequently used during spawning (5 of 10 species, Table 4). However, here muscle carbohydrates and proteins were of similar importance (4 and 3 species, respectively), followed by lipid reserves (4 of 10 species) from all three somatic tissues.

TABLE 4.

Proportion of scallop species ($n = 13$) using different biochemical components (and the primary source tissue) to support gonad maturation and spawning.

Reproductive Process	Carbohydrates	Proteins	Lipids
Gonad maturation	82% (88% muscle)	55% (66% muscle)	55% (70% digestive gland)
Spawning	50% (80% muscle)	50% (60% muscle)	40% (from all three tissues)

The reliance of scallops on the adductor muscle as an energy storage site has been suggested to reflect the monomyarian condition, which requires a readily available source of energy to support muscle contraction during swimming and escape responses (Ansell 1974). Muscle contraction is initially supported by ATP production from arginine phosphate, with octopine production from glycogen occurring in the final stages of exhaustive escape responses (Thompson et al. 1980, Livingstone et al. 1981, Chih & Ellington 1983, and Chih & Ellington 1986). The escape response and swimming performance would thus be largely maintained even after reduction of muscle glycogen levels. Recuperation from exhaustion relies on glycolytic breakdown of glycogen with ensuing octopine production (Thompson et al. 1980, Livingstone et al. 1981, Chih & Ellington 1983, and Chih & Ellington 1986). The preferential mobilization of carbohydrates for gonadal growth should primarily slow the capacity to renew escape responses. Effectively, the marked reduction of muscle glycogen during gonad maturation in *C. islandica* and *E. ziczac* is paralleled by decreases in muscle metabolic capacities and in recuperation from exhaustive exercise (Brokordt et al. 2000a and Brokordt et al. 2000b). On the other hand, in most scallops the adductor muscle contains 2–10-fold more protein than carbohydrate, suggesting that the mobilization of an energetically equivalent quantity of protein would cause a proportionally smaller impact on adductor muscle performance. However, several factors argue against the use of

protein. Muscle proteins have functional roles that make them an energetic reserve of last resort. Thus, mobilization of structural proteins (50%–60% of muscle proteins in *C. islandica* and *E. ziczac* (Brokordt et al. 2000a and Brokordt et al. 2000b)) would reduce muscle integrity. Even though soluble proteins are twice as abundant as muscle glycogen in *C. islandica* (Brokordt et al. 2000a), glycogen is used first, likely a reflection of the functional importance of these soluble proteins. Furthermore, the degradation of glycogen into sugar units and their use for the production of gonad carbohydrates or triglycerides would be metabolically simpler and energetically cheaper than the breakdown and resynthesis of proteins. Similar arguments underlie the use of lipids during oocyte production. Explanations of the metabolic strategies underlying inter-tissue transfers of material and energy and reliance on dietary sources must integrate not only the energetic value of the components and the functional consequences of their use (ie, decreased behavioral responses) but also the energetic cost of their production.

ACKNOWLEDGMENTS

This study was supported by a grant from NSERC to HG. The authors thank Dominique Lapointe and Marie-Eve Fortin for careful technical assistance and to Martin Guay for the sampling of the scallops.

ESTIMATION OF SEA SCALLOP ABUNDANCE USING A VIDEO SURVEY IN OFF-SHORE US WATERS

KEVIN D. E. STOKESBURY,* BRADLEY P. HARRIS, MICHAEL C. MARINO II AND
JACOB I. NOGUEIRA

School for Marine Science and Technology, University of Massachusetts Dartmouth, 706 South Rodney
French Boulevard, New Bedford, Massachusetts, 02744-1221

ABSTRACT A video survey was conducted from May 28, 2003, to August 23, 2003, to provide spatially explicit estimates of sea scallop density and size distributions along the off-shore northeast waters of the United States. Sea scallop (*Placopecten magellanicus*) densities in the Mid-Atlantic (26,270 km²) and Georges Bank (28,523 km²) ranged from 0.04 to 0.79 and 0.09 to 0.26 scallop · m⁻², respectively, and represented approximately 217,520 mt tons of scallop meats (approximately US\$2.4 billion). Sea scallops were highly aggregated in areas closed to mobile fishing gear. In the Georges Bank closed areas the proportion of sea scallop pre-recruits (<90 mm shell height) was low and sufficient to replace the adult population at an instantaneous mortality rate of 0.10 but not at a higher rate. A large number of prerecruit scallops were observed in the southern portion of the Hudson Canyon closed area extending south into open waters. Sea stars outnumbered sea scallops (approximately 39 to 16 billion, respectively) although most were small (20- to 40-mm arm length). Sea stars may be responsible for sea scallop mortality in the southern portion of Closed Area II.

KEY WORDS: sea scallop, *Placopecten magellanicus*, video, systematic survey, sea stars, Georges Bank, mid-Atlantic

INTRODUCTION

Large densities of sea scallops, *Placopecten magellanicus* (Gmelin 1791), exist in areas of the Mid-Atlantic and Georges Bank that have been closed to commercial scallop dredging since 1998 and 1994, respectively. Three areas on Georges Bank were closed to all mobile fishing gear to protect declining groundfish stocks, and two areas in the Mid-Atlantic were closed to enhance scallop abundance (Murawski et al. 2000, Hart 2001, 2003). To use the sea scallop resource in these areas, the New England Fisheries Management Council and National Marine Fisheries Service (NMFS) are developing fisheries management plans that require spatially explicit information.

Estimates of sea scallop abundance are made using dredge surveys, which require an estimate of dredge efficiency to determine absolute densities (Caddy 1989, Murawski et al. 2000). Using a video survey eliminates the error associated with the dredge efficiency as the actual number of scallops within the sample area is counted (Stokesbury 2002). Furthermore, this system provides spatially explicit information on the sea floor and marine benthic community (Stokesbury 2002).

The objective of this study was to provide spatially explicit, accurate, precise, absolute estimates of sea scallop density and size distributions along the off-shore northeast waters of the United States. Detailed information on the sediment and marine benthic habitat associated with the sea scallop fishing grounds will be presented in a future publication.

MATERIALS AND METHODS

In preparation for the survey Letters of Authorization for scientific research were obtained from the NMFS for each participating sea scallop-fishing vessel. Commercial fishing gear was removed from the fishing vessels prior to conducting each six-day cruise. A mobile studio, including monitors and S-VHS video recorders for each camera, a monitor for the Captain controlling the vessel's hydraulic winches to deploy the pyramid, a laptop

computer with Arcpad GIS[®] software integrated with a differential global positioning system with a WAAS receiver, and a laptop computer for data entry, was assembled in the wheelhouse. The survey grid was plotted prior to the cruise in Arcpad GIS[®]. Two scientists, a captain, mate and one deck hand were able to survey stations continually, completing 20 to 30 stations every 24 h.

The SMAST sampling pyramid was deployed from the scallop fishing vessels (Fig. 1). Two cameras mounted vertically on the pyramid at a height of 700 and 1575 mm above the pyramid's base provided quadrat sizes of 0.595 and 2.841 m², respectively (Figs. 2 and 3). A third camera mounted horizontally 50 mm above the pyramid base provided a side view across the sample area (Fig. 4). All sea scallops were counted, including those along the edge of the quadrat image that were only partially visible. To correct for this edge effect 75 mm, based on the average shell height of the scallops observed, was added to each edge of the quadrat image providing quadrat sizes of 0.788 and 3.235 m² (Stokesbury 2002).

Our primary quadrat sample size was 3.235 m², but one scallop per quadrat (0.31 scallop · m⁻²) is above minimal commercial densities (Caddy 1989, Brand 1991, Thouzeau et al. 1991, Stokesbury & Himmelman 1993, Stokesbury 2002). Therefore, at each station we collected four quadrat samples increasing the sample area to 12.94 m². The vessel stopped at each station and the pyramid was lowered to the sea floor. Footage of the first quadrat was recorded, and then the pyramid was raised so the sea floor could no longer be seen. The vessel drifted approximately 50 m and then the pyramid was lowered to the sea floor again to obtain a second quadrat; this was repeated four times.

We used a centric systematic design to position the stations because it is simple, samples evenly across the entire survey area, and has been successfully used to survey scallops on Georges Bank (Thouzeau et al. 1991, Stokesbury 2002). With this sampling design it is possible to estimate densities of macroinvertebrates within different areas without violating the sampling protocol or paying a statistical penalty for post-stratification. Further the centric systematic design facilitates mapping sea floor sediments and macroinvertebrate distributions.

Stations were positioned on a 5.6 by 5.6 km (3.0 by 3.0 nautical mile) grid overlying historical and present fishing grounds based

Figure 1. The SMAST video sampling pyramid aboard the F/V *Huntress*. The pyramid has a square base 2.2 m per side of 6 cm round iron, arms 2.5 m \times 4.5 cm round iron and weighs approximately 450 kg. It is deployed with the large hydraulic winch used in the scallop fishing industry while a second tension sensitive hydraulic winch controls the electronic cable. Rubber rings (three sets of eight rings, each 20 cm diameter, 5 cm thickness, per side) were placed on the base of this pyramid to prevent damage during deployment and provide gentle landings on the sea floor. Three underwater cameras (Deepsea Power & Light® multi-Seacam) and nine 100-w lights (Deepsea Power & Light® multi-Sealite) were attached to the pyramid.

on information from commercial fishermen and the Vessel Monitoring System (Rago et al. 2000: Fig. 5). We selected the distance of 5.6 km between stations because it was logistically feasible and allowed an accurate estimate of the mean sea scallop density with little loss of precision. Estimates of mean sea scallop $\cdot m^{-2}$ from the Nantucket Lightship area, surveyed in 2002, were similar for distances between stations ranging from 1.6 to 5.6 km; the standard error (SE) increased because of reduced sample size but the coefficients of variation (CV) were still low, 0.62 (SE = 0.057, CV = 9.3%) and 0.62 (SE = 0.101, CV = 16.3%) scallop $\cdot m^{-2}$, respectively. For distances greater than 5.6 km between stations the estimated means of scallop $\cdot m^{-2}$ as well as the standard errors and coefficients of variation increased, for example the mean was 0.75 scallop $\cdot m^{-2}$ (SE = 0.300, CV = 40.1%) for a 9.3-km station grid.

Video footage of the sea floor was recorded on S-VHS tapes. For each quadrat the time, depth, number of live and dead scallops, and latitude and longitude were recorded (Fig. 6). After each survey the videotapes were reviewed in the laboratory and an image of each quadrat was digitized and saved using Image Pro Plus®

Figure 2. The 2.8-m² quadrat image digitized from video footage of sea scallops, *Placopecten magellanicus*, in the Nantucket Lightship Area (NLSA). Every quadrat image from this camera had a 200-mm mark clearly displayed on the lead-line cross.

software (TIF file format). Within each quadrat macroinvertebrates and fish were counted and the substrate was identified (Stokesbury 2002). Counts were standardized to individuals $\cdot m^{-2}$.

Sea scallop shell heights (mm) were measured using Image Pro Plus® software (Fig. 7). An equation (Equation 1) to correct for the curve of the camera lens was applied to each shell height measurement. This equation was estimated and verified with laboratory and field experiments that indicated a measuring error of less than 5% (author's unpublished data).

$$c = sh \sqrt{\frac{(x)^2 + (y)^2}{(y)^2}} \quad (1)$$

where:

c = corrected shell height (mm)

sh = shell height (mm) measured using image pro

y = vertical camera height from the base of the sampling pyramid

x = distance from the center of the quadrat (mm)

Mean densities and standard errors of scallops were calculated using equations for a two-stage sampling design (Cochran 1977).

Figure 3. The 0.6-m² quadrat image digitized from video footage of sea scallop, *Placopecten magellanicus*, prerecruits in the southern portion of the Hudson Canyon Closed Area.

Figure 4. Sessile macroinvertebrates, including the finger sponge, *Haliciona oculata* (Linnaeus 1759) and bryozoa, probably *Flustra foliacea* (Linnaeus 1738), digitized from video footage recorded with the side view camera. Note the pyramid frame and lights in the background.

The mean of the total sample is:

$$\bar{\bar{x}} = \sum_{i=1}^n \left(\frac{\bar{x}_i}{n} \right) \quad (2)$$

where:

n = primary sample units (stations)

\bar{x}_i = sample mean per element (quadrat) in primary unit i (stations)

$\bar{\bar{x}}$ = the mean over the two-stages.

The standard error of this mean is:

$$S.E.(\bar{\bar{x}}) = \sqrt{\frac{1}{n} (s^2)} \quad (3)$$

where:

$s^2 = \sum^n (\bar{x}_i - \bar{\bar{x}})^2 / (n - 1)$ = variance among primary unit (stations) means.

Because the sampling fractions were small, hundreds of scallops sampled compared with millions of scallops in the area, the finite population corrections were omitted simplifying the estimation of the standard error (Cochran 1977).

To examine the effect of variation between elements in the two-stage sampling design, sampling four quadrats per station, we created a simple formula in Excel (Microsoft, Seattle, WA) that randomly selected one of the four quadrats from each station and then calculated the means and variances for each survey area. This removed the subsampling component of the two-stage sampling design reducing it to an unaligned systematic sample, which is often superior to stratified random sampling (Cochran 1977). Using the Excel formula we generated 240 estimates of the means and determined the standard error (Glantz 2002).

The absolute number of scallops within a survey area was calculated by multiplying the mean number of scallops $\cdot m^{-2}$ by the total area surveyed (Stokesbury 2002). Distributions of scallops $\cdot m^{-2}$ were plotted using ArcGIS® software. Estimates of scallop meat weight (w) were derived from shell height (sh) frequencies for each area and length/weight regressions for each area to the nearest season and time of the survey. These equations were calculated from live dissections of sea scallops collected during

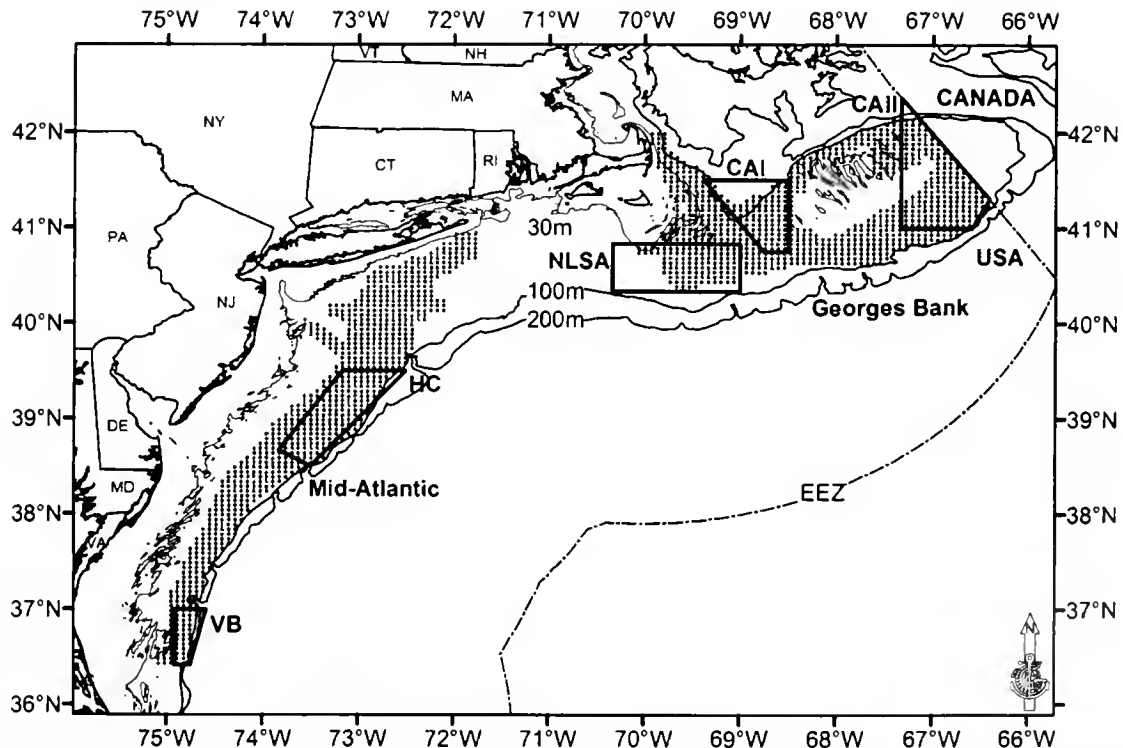

Figure 5. The SMAST 2003 video survey-sampling grid ranging from Virginia Beach, VA, to Cape Cod, MA, and to the Canada/US border (the hauge line) on Georges Bank. From May 28 to August 23, 2003, 1,775 stations, with four quadrats per station, were sampled on this 5.6 \times 5.6-km grid. NLSA, Closed Area I (CAI), Closed Area II (CAII), Hudson Canyon (HC), closed area, and Virginia Beach closed area (VB) are enclosed with a solid line; the Economic Exclusive Zone (EEZ) is also shown.

fishing trips from open areas and from vessels that participated in the Sea Scallop Exemption Fishery in each of the closed areas (Table 2; Nantucket Lightship Area $w = 1.21 \times 10^{-5} \cdot sh^{3.1062}$, CAI $w = 8.21 \times 10^{-6} \cdot sh^{3.1321}$, CAII $w = 1.52 \times 10^{-5} \cdot sh^{3.0443}$, Georges Bank open $w = 7.38 \times 10^{-6} \cdot sh^{3.1559}$, mid-Atlantic, HC and VA $w = 1.63 \times 10^{-5} \cdot sh^{2.9485}$; author's unpublished data).

RESULTS

The 2003 survey of commercial off-shore sea scallop fishing grounds covered 54,793 km² (16,000 nm²). Sea stars (Asteroidea)

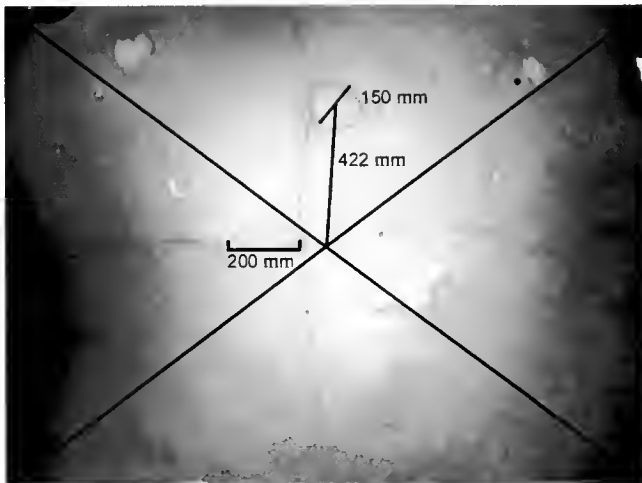

Figure 7. To measure the shell height (mm) of a sea scallop the digitized 2.8-m² quadrat image was imported into Image Pro Plus[®] software. Lines from each corner of the image were drawn to determine the center of the quadrat. The shell height was measured starting at the umbo to the shell margin. The scallop in this image is measured as 150 mm. The distance from the center of the scallop to the center of the quadrat was measured (422 mm, for this scallop). These measurements were entered into the correction equation, $150 \cdot \sqrt{(1572)^2 + (422)^2} / (1572)^2 = 155$ mm, which is the actual shell height of the scallop. Note the palmate sponge, probably *Isodictya palmate* (Lamarck 1814) also in the quadrat and the sand ripple substrate.

were the most abundant macroinvertebrate observed numbering approximately 39 billion, although most individuals were small (20–40 mm arm length) (Table 1). High densities of sea stars occurred in both open and closed areas of Georges Bank and the mid-Atlantic with the highest density in the Nantucket Lightship area (Table 1).

Sea scallops, *Placopecten magellanicus*, were the second most abundant macroinvertebrate observed numbering approximately 16 billion scallops representing approximately 217,520 mt tons of scallop meats (Table 2).

The mid-Atlantic contained the greatest number of sea scallops observed in the 2003 survey, 74% (Table 2, Fig. 8). In the mid-Atlantic 23% of the area surveyed is closed to scallop fishing. The lowest and highest densities of scallops in the mid-Atlantic were in the Virginia Beach and Hudson Canyon closed areas, 0.04 and 0.79 scallop \cdot m⁻², respectively (Table 2, Fig. 9). Assuming that stations with at least one scallop observed in four quadrats represents scallop habitat (Stokesbury 2002) the densities increased to 0.09 (SE = 0.007) to 1.08 (SE = 0.338) scallop \cdot m⁻². Sea scallops were aggregated in the Hudson Canyon closed area, which contained 33% of the scallops observed in the mid-Atlantic, representing 36% of the scallop meat weight, (comparison of the number of scallops observed in open and closed areas, $df = 1$, $\chi^2 = 290$, $P < 0.001$).

The mid-Atlantic contained only 46% of the total scallop resource meat weight, (Georges Bank and mid-Atlantic combined; Table 2). This low meat weight compared with the high density of scallops is due to a large recruitment of scallops that were below commercially harvestable size (90-mm shell height equal to a 3.5" ring mesh size in the scallop dredge; Fig. 9). In the Hudson Canyon closed area and mid-Atlantic open area 62% and 69% of the scallops measured were less than 90 mm (Fig. 9).

Sea scallops were highly aggregated on Georges Bank with 66% of the all the individuals observed, representing 82% of the scallop meat weight, within the closed areas (comparison of the number of scallops observed in open and closed areas, $df = 1$,

Meat weight (g) estimates, based on the shell height frequency observed in each area and the shell height/meat weight regression, and area surveyed (km²), provided the metric tons of meat weight in each area. Estimates were calculated for the Nantucket Lightship Area (NLSA), Closed Area I (CAI), Closed Area II (CAII), Hudson Canyon (HC) and Virginia Beach (VB) closed areas and open areas of Georges Bank and the mid-Atlantic.

$\chi^2 = 330$, $P < 0.001$; Table 2, Fig. 10). Densities of sea scallops ranged between 0.16 and 0.26 scallop \cdot m⁻² in the closed areas of Georges Bank compared with 0.09 scallop \cdot m⁻² in the open area (Table 2). Sea scallop densities increased to 0.38 (SE = 0.071) to 0.62 (SE = 0.094) scallop \cdot m⁻² in the closed areas and 0.23 (SE = 0.0175) scallop \cdot m⁻² in the open area for stations where at least one scallop was observed within four quadrats.

The majority of scallops in the open area of Georges Bank, 59%, were below harvestable size (<90 mm shell height; Fig. 9). The majority of sea scallops in the closed areas were very large with 77%, 87%, and 87% of the scallops greater than 90-mm shell height in Closed Area I, Closed Area II, and the Nantucket Lightship Area, respectively (Fig. 9).

The two-stage sampling technique provided the same means as the unaligned systematic sample (Table 2). In all areas the CV decreased using the unaligned systematic sample except for the Virginia Beach closed area where both the number of stations and number of scallops observed were small (Table 2).

Scallops that had died of natural causes were identifiable in the video footage as the two shells were still attached at the umbo. The highest number of dead sea scallops occurred in the southern portion of Closed Area II (Fig. 11). A dense aggregation of large sea stars (9.20 sea star \cdot m⁻², mean arm length 123.5 mm, SD = 35.39) was also observed in this area with the dead scallops suggesting a localized high natural mortality event (Fig. 12).

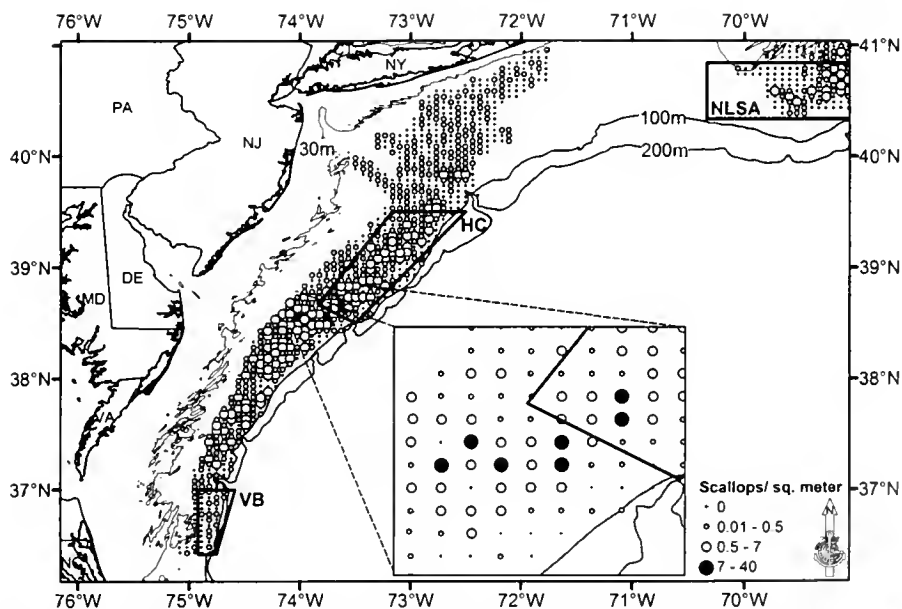

Figure 8. Sea scallop, *Placopecten magellanicus*, distributions (scallop \cdot m⁻²) in the mid-Atlantic observed during the SMAST video survey. The insert shows the extremely high densities (>7 scallop \cdot m⁻²) of pre-recruit scallops observed in the southern portion of the HC closed area extending south into the open area.

DISCUSSION

We estimate that the sea scallop, *Placopecten magellanicus*, resource in the off-shore waters of the Northeastern United States contain approximately 16 billion individuals, representing approximately 217,520 mt tons of scallop meats. The sea scallop biomass on Georges Bank in United States waters alone is 3.5 times greater than the average biomass from 1977 to 1988 for all of Georges Bank (31,500 mt tons, Canadian and United States portions combined; McGarvey et al. 1992). In the previous fishing year (March 2002 to February 2003) the sea scallop fishery harvested 23,237 mt tons of sea scallop meats, equivalent to 11% of the biomass surveyed in the 2003 survey (NMFS Fishery Statistics Report).

The high biomass is primarily a result of high densities and very large scallops within the closed areas of the mid-Atlantic and Georges Bank. However, sea scallops abundances have increased in the open areas as well.

The increase in numbers of scallops in the mid-Atlantic is the result of an extremely large recruitment of juvenile scallops. Periodically large year classes of sea scallops have occurred throughout the history of the fishery and are believed to result from favorable environmental conditions (Serchuk et al. 1979, Caddy 1989). Caddy (1989) states that scallop biomasses have shown wide fluctuations from year to year that are not all the result of fishing. The sea scallop fishery falls outside the stable classification and represents a cyclical, irregular or spasmodic fisheries time series depending on the geographic location of the bed (Caddy & Gulland 1983, Caddy 1989).

The high abundance of large scallops within the closed areas may be producing many more larval scallops than in previous years. Sinclair et al. (1985), Caddy (1989) and McGarvey et al. (1992) emphasize the importance of larger size on the fecundity-per-recruit relationship. McGarvey et al. (1993) suggest that a stock-recruitment relationship exists for +5 y old sea scallops but that the fishery removes the majority of scallops greater than age 3.25 y. The sea scallop densities and sizes we observed exceed previously recorded densities and sizes over large geographic areas (Stokesbury 2002).

The high abundance of large scallops within the closed areas on Georges Bank may also be inhibiting recruitment. Few prerecruit scallops (<90-mm shell height) were observed in these closed areas. Replacement of the adult scallop stock is barely occurring in the Nantucket Lightship Area and Closed Area II with the prerecruit densities observed in 2003, using an instantaneous mortality rate of 0.10 and assuming a 17 y life span (Caddy 1989). If the instantaneous mortality rate is slightly higher than 0.10, for example 0.12, then the 2003 recruits would not sustain the adult scallop population at its present density.

A sea scallop mass-mortality event may be occurring in the southern portion of Closed Area II due to sea star predation. Here the highest densities of large sea stars and dead scallops occurred. The NMFS observed a high instantaneous mortality rate ($M = 0.6$) in this area although there is considerable uncertainty in the estimate due to the year-to-year variability of the survey (the mean

Figure 12. A high density of large Sea stars, *Asterias* spp., and two sea scallops observed in the southern portion of CAII June 27, 2003.

number of scallops per tow was 1255 in 2002 and 698 in 2003, >40 and >70 mm shell heights, respectively; D. Hart, personal communication). Between 1928 and 1961 nine mass mortalities occurred in the Gulf of St. Lawrence populations (Dickie & Medcof 1963). The more devastating widespread mass mortalities (up to 80% of the population) were attributed to water temperatures exceeding the upper lethal limits for scallops. The less severe mass mortalities (up to 25%) were attributed to sea star predation (Dickie & Medcof 1963).

Sea stars were twice as abundant as sea scallops in 2003, although many were very small suggesting a new recruitment. In our previous surveys of Georges Bank and the Mid-Atlantic sea scallops far outnumbered sea stars. Therefore, localized high natural mortality caused by sea star predation may be an increasing concern for the sea scallop fishery. We are examining predator-prey distributions and interactions and spatial variation in natural mortality.

The video survey technique is fast, accurate, precise, and provides information on the biology of scallops and the associated habitat without disturbing the sea floor (Stokesbury 2002). The two-stage sampling technique and the unaligned systematic sample provided similar means and low coefficients of variation compared with many invertebrate surveys (Krebs 1989).

The 2003 video survey was a success due to the strong collaboration and participation of the sea scallop fishing fleet and

supporting industries. Preliminary data from this survey have been presented to the New England Fisheries Management Council and the NMFS. A closure that will protect the area of high sea scallop recruitment in the southern portion of the Hudson Canyon closed area extending south into open waters has been proposed in the recent sea scallop fishery management plan. Further, the southern portion of Closed Area II may be opened earlier than scheduled due to the high natural mortality observed in this area.

SITE SELECTION FOR OYSTER HABITAT REHABILITATION IN THE VIRGINIA PORTION OF THE CHESAPEAKE BAY: A COMMENTARY

ROGER MANN* AND DAVID A. EVANS

Virginia Institute of Marine Science, College of William and Mary, Gloucester Point, Virginia 23062

ABSTRACT A significant body of knowledge has been generated during the past decade on disease tolerance of the native oyster *Crassostrea virginica*. A major opportunity to move into a large-scale field application phase of that knowledge has been presented by a 10-y commitment by the U.S. Army Corps of Engineers (ACOE) to a partnership in Virginia focused on widespread restoration of oyster resources for ecological purposes. The partnership involves ACOE, the Virginia Institute of Marine Science (VIMS), the Virginia Marine Resources Commission (VMRC), and the Chesapeake Bay Foundation (CBF). This collaboration will effect a sequenced restoration effort involving site selection, site restoration, brood stock addition from known genetic lines, evaluation of the stock in the new location for disease tolerance and/or contribution to cumulative recruitment, and, through adaptive management, will seek to optimize the widespread restoration of the oyster populations in Virginia. This contribution focuses on the importance of site selection in this effort, paying particular attention to the roles of (1) demographics and disease status on fecundity of brood stock, (2) larval feeding and growth rate in high-turbidity conditions typical of low-salinity sanctuaries from disease, (3) ontogenetic changes in larval behavior in such conditions, and (4) the role of estuarine circulation in retaining larvae in regions suitable for subsequent recruitment. We argue that while efforts to develop disease-tolerant brood stock may contribute to restoration efforts, without parallel guiding knowledge of items 1–4 above, efforts at restoration will at best be serendipitous, at worst be doomed to failure, and that site selection in restoration is crucial to success.

KEY WORDS: Chesapeake Bay, *Crassostrea virginica*, restoration

INTRODUCTION

A major opportunity to move into a large-scale field application phase of advances in disease tolerance of the native oyster *Crassostrea virginica* has been presented by a 10-y commitment by the U.S. Army Corps of Engineers (ACOE) to a partnership in Virginia focused on widespread restoration of oyster resources for ecological purposes. The partnership involves ACOE, the Virginia Institute of Marine Science (VIMS), the Virginia Marine Resources Commission (VMRC), and the Chesapeake Bay Foundation (CBF). This collaboration will effect a sequenced restoration effort involving site selection, site restoration, brood stock addition from known genetic lines, evaluation of the stock in the new location for disease tolerance and/or contribution to cumulative recruitment, and, through adaptive management, will seek to optimize the widespread restoration of the oyster populations in Virginia.

This contribution focuses on site selection, paying particular attention to the role of oyster demographics, fecundity, larval biology, and estuarine circulation in determining the probable success of long-term recruitment. A temporal context is important in developing the rationale for the proposed study. Oysters are a primitive molluscan form with an extensive fossil lineage. They use a primitive planktotrophic larval form. The complex life history of the species, the remarkable physiologic range of tolerance of the adult form and its individual longevity, have served it well in coastal regions that exhibit ephemeral (in geological time) appearance and disappearance of estuaries in dynamic coastal temperate climate regions. Larvae serve as the initial colonizing life stages as estuaries are formed—it is the behavior of these larvae in complex estuarine circulation that facilitates this initial invasion. The adult form establishes long-term residency of the estuary by providing a local larval source, ensuring continued recruitment when conditions allow, and accreting reefs to facilitate recruitment of subsequent generations. These are classic examples of source-

sink dynamics (Pulliam 1988, Pulliam et al. 1991, Pulliam et al. 1992, Hanski 1994) during periods of thousands of years. To persist, the adult form must survive the annual temporal variations in a local environment, whereas the larvae survive only a narrow window in that time frame. Oysters are a classic example of the evolution of two distinctly successful evolutionary life stages that are different in their individual environmental tolerances and optima. The complex life history and ancient lineage of oysters argue that the traits of the larval and adult forms are highly conserved [see contributions in McEdwards (1991), Hall & Wake (1999)]. Furthermore, within the conservative limitations of both life history stages, it is realistic to expect limited phenotypic plasticity in response to rapidly (on an evolutionary time scale) changing local environments. Indeed, in a classic evolutionary sense, it is rapid changes in local environments that lead to local extinction.

Consider the situation faced by a collaboration of scientists and managers in restoration of the Chesapeake Bay oyster resource. The watershed has been irretrievably altered in the short period since Colonial settlement with accompanying change in water quality in an absolute sense and in seasonal runoff variability. The estuarine environment has been and continues to be radically altered by fishing, shoreline development, and maintenance of navigable channels. Such rapid change in local conditions would be a stress contributing to local extinction. In addition, two diseases (*Perkinsus* and *Haplosporidium* = MSX) are now endemic in the local populations, one of which (MSX) did not co-evolve with the local oyster populations. Such rapid changes in disease stress could contribute to local extinction. Extant oyster populations are limited to low-salinity sanctuaries. We know that oysters survive over a remarkable salinity range, but we do not know the extent of the low-salinity stress as a suboptimal environment—the abundant oyster literature is remarkably devoid of good data on low-salinity responses because so much literature is devoted to response in optimal environments. The low-salinity sanctuaries are in closer proximity to increasingly turbid regions of the upper estuary that adversely affect optimal feeding in both life-history stages, arguably more so in the larval stage. The exile of reproductive adults

*Corresponding author. E-mail: rmann@vims.edu

and larvae to low-salinity, turbid regions would again be a stress contributing to local extinction. Given this litany of stresses, it is indeed surprising that oysters have not become locally extinct.

Placement of three-dimensional reef sanctuaries and enhanced shell plantings (two-dimensional extensive substrate enhancement) cannot have the consistent expectation of stimulating long-term cumulative recruitment when placement is based on geological footprints of reefs that successfully survived for millennia prior to the radical environmental changes that have occurred since Colonial settlement. The environments in which those reefs formed reflect the conservative evolutionary traits of the native oyster—they do not reflect the current, post-Colonial local environment. A recent comprehensive map-based illustration of restoration activity to date in Virginia waters is given by Berman et al. (2002). Though the placement of reefs to date has been guided by a cumulative commonsense approach to data on both long-term disease impact and a much longer term history of oyster productivity (e.g., Baylor 1894, Haven et al. 1981), it has resulted in highly variable temporal (interannual) and spatial success in recruitment [see Bartol & Mann (1997), Luckenbach et al. (1999), Mann (2000), Mann (2001)]. This should not be surprising to us in that the larval and early postlarval stages are challenged by conditions that, we argue, are commensurate with local extinction. If we are to be successful in restoration of oyster populations, we must understand the limitations of the larval forms within this new (to them) suite of adverse environmental variables.

ILLUSTRATING THE CHALLENGE NUMERICALLY, PART I: COMPONENTS OF THE CALCULATION

The relative importance of brood stock fecundity, larval growth and survival, and larval retention in contributing to the recruitment of a subsequent generation can be illustrated by a numerical approach to life cycle descriptions. Originally and elegantly described by Paulik (1973), this approach was adapted by Mann and Evans (1998) in estimation of oyster, *Crassostrea virginica*, standing stock, larval production, and advective loss in relation to observed recruitment in the James River, Virginia. The current illustration simplifies this approach using a virtual population to examine the effects of three parameters on recruitment in subsequent generations. These parameters are (1) varying egg production by varying age-specific mortality of the parent population as a proxy for disease impacts, (2) varying duration of larval period in response to suboptimal feeding conditions, and (3) varying loss to advection related to estuarine tidal exchange. To summarize and simplify Mann and Evans (1998), recruitment, R , to the 25-mm size class is estimated from larval supply thus:

$$R = (F_{\text{tot}} \times F_q \times F_s \times F_d \times F_f) \times (1 - \text{exch})^{2d} \times (1 - L_{\text{mort}})^d \times P_{\text{sub}} \times P_{\text{foul}} \times P_{\text{met}} \times (1 - J_{\text{mort}})^{dp}$$

F_{tot} is total egg production and is estimated from size-specific fecundity. It is a cumulative total for all individuals (F_{ind}) in all size classes and typically estimated from length:dry weight estimators. In the current illustration, all sizes below 40 mm are considered young of the year (spat) and do not contribute to spawning, and fecundity is estimated from relationships given in Thompson et al. (1996) and Mann and Evans (1998). F_q is a sex ratio modifier. Cox and Mann (1992) suggest parity in sex ratio. Given the

lack of other data, a single sex ratio modifier, F_q , with a value of 0.5 (50% female in all size classes) is used in this illustration. F_s , F_{ind} and hence F_{tot} can be modified based on salinity (S) effects. Mann and Evans (1998) suggested the following estimators for F_s :

$$\text{if } S > 13.5, F_s = 1.0; \text{ if } S < 13.5, \text{ then } F_s = [(S - 8.0)/(13.5 - 8.0)] \times 1.0 = (S - 8.0)/5.5$$

F_d modifies fecundity for disease effects with values ranging from 1.0 to 0.0. In the current illustration, it varies from 1.0 to 0.75 (a 25% reduction based on disease impact). F_f describes a density-dependent multiplier for fertilization efficiency with values from 1.0 (100% fertilization) to 0.0 (no fertilization). It is based on Levitan (1991) where:

$$\begin{aligned} \log \% \text{ fertilization} &= [0.72(\log \text{OD}) + 0.49] \text{ or,} \\ \% \text{ fertilization} &= [0.49 \times \text{OD}^{0.72}] \end{aligned}$$

where OD is oyster density in numbers m^{-2} . In the current illustration, it is rewritten thus:

$$F_f = 0.0049 \times \text{OD}^{0.72}$$

Production of larvae (strictly speaking embryos or fertilized eggs) m^{-2} is therefore estimated by $(F_{\text{tot}} \times F_q \times F_s \times F_d \times F_f)$ in units of larvae m^{-2} .

Mann and Evans (1998) estimated retention of the larvae within the James River during planktonic development using the three-dimensional flow model of Hamrick (Hamrick 1992a, Hamrick 1992b) to provide source and sink data at scales within the estuary. For the current illustration, a simple dilution function, $(1 - \text{exch})^{2d}$, is used that assumes uniform dispersal within the estuary and proportional loss on each tidal cycle; that is, larvae are assumed to be neutrally buoyant and exert passive swimming behavior in response to oriented stimuli. Thus, larval numbers decreased with days with the duration of planktonic development by the function where exch is proportional volumes exchanged on each tide. The value of exch varies in the current study between 0.1 and 0.2 (0.2 equals a 20% exchange per tidal cycle), and d is the duration of the larval development (= planktonic) period. The correction $2d$ is used with a simple assumption of two tidal exchanges per day. In the current study, d varies from an optimum of 21 days, based on values from Mann et al. (1994), Mann and Evans (1998), Bochenek et al. (2001), and Powell et al. (2002), to a suboptimal value of 25 days based on assumed reduction of feeding and hence growth in low-salinity and/or high-turbidity regions.

The function $(1 - L_{\text{mort}})^d$ estimates larval mortality in the water column. L_{mort} is the daily larval mortality rate [a proportional value between 1.0 (all died) and 0.0 (no mortality)]. Survival is $(1 - L_{\text{mort}})$ for a period of one day or $(1 - L_{\text{mort}})^d$ for a "d" day planktonic development period. For the current illustration, L_{mort} is set at 0.05, 0.06, 0.07, 0.1, and an extreme value of 0.25. The decreasing exponential relationship ensures a gradual decreasingly sensitive response to increasing values of d . Modification of the original number of larvae to account for dispersal loss and mortality provides an estimate of larvae surviving to immediate premetamorphic size. The transition to an attached benthic form requires successful location of substrate, that the substrate not be occluded by competing organisms, and that the larvae have sufficient energy reserves to complete the metamorphosis to a juvenile feeding form.

P_{sub} , a dimensionless modifier with a value between 1.0 and 0.0, describes the probability of finding suitable substrate. The time scale and availability of shell substrate is crucial to successful recruitment (Morales-Alamo & Mann 1990). Consider that a shell layer 1-cm thick covering 1 m² of bottom has a volume of 10 L. For the current illustration, a premise is adopted that a shell layer a minimum of 1-cm thick is required to offer a suitable substrate. P_{sub} is estimated thus:

$$\text{If shell volume} > 10 \text{ L m}^{-2}, \quad P_{sub} = 1.0$$

$$\text{If shell volume} < 10 \text{ L m}^{-2}, \quad P_{sub} = 0.1 \times \text{shell volume (in L)}$$

P_{foul} describes proportional occupation of the substrate by competing organisms and varies between 1.0 (no fouling) to 0.0 (complete preclusion of settlement). Rheinhardt and Mann (1990) suggest a value of $P_{foul} = 0.33$ based on field studies in the James River. For the current illustration, a constant value of 1.0 is used.

P_{met} describes the probability of successful completion of metamorphosis to the attached form on a 1.0 (all survive) to 0.0 (no survival) scale. For the current application, the value is set at 0.20.

Recruitment, R , to the benthos is therefore estimated from larval supply values by incorporating $(1 - exch)^{2d}$, $(1 - L_{mort})^d$, P_{sub} , P_{foul} , and P_{met} thus:

$$R = [(F_{tot} \times F_q \times F_s \times F_d \times F_f) \times (1 - exch)^{2d} \times (1 - L_{mort})^d \times P_{sub} \times P_{foul} \times P_{met}]$$

$(1 - J_{mort})^{dp}$ modifies this estimator for postsettlement mortality and growth rates, both of which are known to be size dependent (Roegner & Mann 1995). Mann and Evans (1998) describe daily juvenile mortality rate as J_{mort} (proportional with a value between 0.0 and 1.0). Survival is $(1 - J_{mort})^{dp}$, where dp is the number of days to grow to a defined size. Based on values of J_{mort} in Roegner and Mann (1995), Mann and Evans (1998) suggest a cumulative mortality to 8-mm length of 93% during a 28-day period, a calculated value for J_{mort} of 0.09. Thus, $(1 - J_{mort})^{dp}$ for the current study is set at 0.07 to 8 mm length. Above this, length of J_{mort} is lower and set at 0.05 for another 25 days until a size of 25 mm when the surviving individuals are considered recruits to the subsequent generation (Eggleston 1990). For the current illustration, $(1 - J_{mort})^{dp}$ incorporates two mortality rates with a cumulative mortality value for the premetamorphosis larvae to 25-mm size class, including a P_{met} value of 0.20 is 99.84%, or a proportional survival of 0.0016.

ILLUSTRATING THE CHALLENGE NUMERICALLY, PART 2: DEVELOPING A GROWTH AND AGE VERSUS LENGTH ESTIMATOR

There are surprisingly few studies of oyster growth rate in the field in the Chesapeake Bay that can be directly related to expected growth on the bottom in reef situations. There are no such prior studies in the upper James River. For the current application, we used data from a growth study using two populations of naturally settled oyster spat collected in the James River in 1992. The populations were collected from dredge hauls on separate days and were thus treated as replicates. Spat on shells were placed in plastic mesh cages on the bottom at Horsehead reef in the upper James River [see Haven & Whitcomb (1983), Berman et al. (2002)]. Approximately 200 oysters were contained in each of three cages. Population #1 was collected on 10/15/92 contained in two cages, population #2 was collected on 11/11/92 and contained in one

cage. Population #1 was contained in two rather than one tray because of the mass of shell to which the oysters were attached. Measurements of length were made at regular intervals for random samples of oysters from within each cage(s) for the period 10/15/92–7/27/93 for population #1, and for the period 11/11/92–1/28/93 for population #2. After these respective periods, all oysters were measured (Table 1). Data for population #1 was pooled from both cages to avoid pseudoreplication. At sampling events, data were also collected on water temperature and salinity. A description of growth over time is obtained from a plot of time versus the mean length (maximum linear dimension) of the oyster (Fig. 1). The spat on shell were from summer 1992 recruitment but of unknown absolute age, thus time is given in Figure 1 as days after 1/1/92. Oyster growth varies seasonally such that a classic Von Bertalanffy equation describing growth would mask this important seasonal fluctuation. Thus, a modified Von Bertalanffy plot with growth oscillation corresponding to seasonal change in growth rate was used. This takes the following form:

$$Lt = \text{Lin}f. \times \{1 - e^{-k} [(t - t_0) + A - B]\}$$

$$\text{where: } A = C. \times \sin [2 \times \pi \times (t - t_s)] / (2 \times \pi)$$

$$\text{and } B = C \times \sin [2 \times \pi \times (t_0 - t_s)] / (2 \times \pi)$$

where Lt is the estimated length at time t , $\text{Lin}f$ is asymptotic length, set at 120 mm based on field observations, K is the growth constant, t_0 is age at which length is zero, C is the amplitude of the growth oscillation, and t_s is the starting point of the oscillation with respect to $t = 0$ (1/1/1992).

Observed and estimated growth of oysters at Horsehead

Figure 1. Observed and estimated oyster growth at Horsehead Reef, James River, 1992-1995.

The parameters of this function were estimated by fitting a rearranged function to the size increment data of a data set which records serial increase in length over time so that we have values of L_1 , L_2 , and so on. The rearranged function is:

$$L_2 = L_{inf} \times \{1 - (1 - L_1/L_{inf}) \times e^{-K[(t_2 - t_1) + A' - B']}\}$$

where $A' = C \cdot \sin[2 \times \pi \times (t_1 - t_s)/(2 \times \pi)]$,
and $B' = C \cdot \sin[2 \times \pi \times (t_2 - t_s)/(2 \times \pi)]$.

The parameters were estimated for this data set at the following values: $K = 0.204$, $t_0 = 0.36$, and $t_s = 0.608$. From length at age data, a matrix is created of both length and growth rate versus time. Estimated length, $L(t)$, versus time is superimposed on observed data in Figure 1. Estimated growth rate, expressed as mm/month increment, for each year class was calculated and subsequently rearranged as a rate versus temperature matrix. Matrix values were used to generate linear descriptors of monthly growth rate in relation to temperature for each year class. The relationship is in the form: $y = mx + c$ and is expressed as mm/month growth increments. Values are given in Table 2. There is a strong correlation between temperature and growth rate suggesting that the latter can be estimated from the former with a high degree of confidence, despite the obvious influence of seasonally varying factors, such as salinity turbidity and food supply, on growth.

Figure 1 illustrates a limitation of the seasonally oscillating fit equation: the possibility of negative growth rate estimation in the winter months. This is a product of the form of the equation with a positive and a negative component. The values used to generate the equation were means, and if error bars are generated around those means, then the brief period of negative growth inferred in Figure 1 is within the error bars. The negative mean growth rate values are small and are not further adjusted for the current model; however, the question arises of the most suitable form of an oscillating growth estimator, especially in a situation such as the James River where winter temperatures are sufficiently low to cause growth to cease, but the rapid spring rise in temperature results in a similarly rapid transition to a high growth rate. This rapid transition in growth rate may be easily masked in a typical

TABLE 2.

Estimation of size specific growth rate incorporating temperature effects.

Month	Temp (C)	Estimated Monthly Growth Rate (mm/month) = (mx + c) Where x is Mean Temperature

growth study with fixed time intervals. True representation of the transition in growth rate around the time of transition will require increased frequency of sampling.

A point of considerable impact that is illustrated by Figure 1 is the estimated age of James River oysters at 62.5 and 76 mm length, respectively (2.5 and 3.0 inches). Both lengths have been used to discriminate seed from market oysters in the commercial fishery in the decade of the 1990s. Though the popular consensus offered in public discussion of size limits in the James River public oyster fishery is that the difference in age between the two sizes is small, Figure 1 suggests otherwise. Animals may exceed the lower size limit in the age range 3.6-4.2 y, but the inflection of the length versus age curve in the mid-70s-mm range suggest that oysters of greater than 76 mm may be 5.5 or more years old. Thus, the increment from 62.5 to 76 mm length may require as much as two years to attain. The management implications are significant; decreasing the maximum size and subsequently reversing that size limit may require up to two years for stocks to recover to former demographics. Also, decreasing the size limit deprives the population of two extra year classes of spawning adults.

ILLUSTRATING THE PROBLEM NUMERICALLY, PART 3: AN EXAMPLE WITH A VIRTUAL POPULATION

Demographics for a virtual population were generated from a data set describing Horse Head Reef in the upper James River for the period 1994-1998 (R. Mann & J. Wesson, unpublished data shown here as Figs. 2A and 2B). This population was chosen because it was (a) stable over that period with respect to recruitment, total oyster density, and oyster demographics, and (b) suffered essentially no mortality due to disease. The size frequency distribution (in 5-mm size classes) was converted to an age frequency demographic using the age-length estimator described earlier.

The virtual population demography is illustrated in Figure 2C, as a series of populations (A-E inclusive) generated by gradually increasing age-specific mortality (illustrated as cumulative mortality in Fig. 2D) chosen to simulate the effects of increasing disease prevalence and intensity. It is notable that the extreme population, E, represents an approximation of current disease tolerance in the most selected strains under typical disease challenge in medium-

salinity waters. Each virtual population has the 25-mm size class, here considered the young of the year recruits or zero class, set at 100 oyster m^{-2} . This corresponds to the R value for recruitment to the benthos in the previously described estimator. In all simulations, performed as a sequential spreadsheet in Microsoft Excel, the barometer for maintenance recruitment of a subsequent generation is attaining a 25-mm size density of 100 oyster m^{-2} . The simulation was run for a single generation time frame with each of A–E as the starting demographic under various scenarios and the end points illustrated in Figures 2E–2L. Although these are just a subset of the many options that can be run with the simulations, they illustrate the following important points:

- (a) Under low tidal exchange ($exch = 0.10$) and optimum larval development ($d = 21$), the recruitment values are very high even with L_{mort} rates (Fig. 2E). With low L_{mort} rates, population A exhibits values of R approaching two orders of magnitude above a maintenance recruitment. Consider, however, that the scenario uses many optimal

conditions including no reduction in fecundity attributable to salinity, no shell limitation to settlement, and only modest competition for substrate. This is very much an optimal scenario.

- (b) Increasing larval duration by only 4 days ($d = 25$) reduces recruitment considerably (Fig. 2F), but still at least an order of magnitude above maintenance for optimal demographic profiles.
- (c) Increasing tidal loss to 20% drives all recruitment values below the critical 100 m^{-2} even with everything else at optimum (Fig. 2E).
- (d) Reducing fecundity by 25% as a proxy for impact of disease and/or salinity has a proportional effect (Fig. 2F).
- (e) Reducing fecundity by 25% and increasing tidal loss to 15% provides options for all population structure from A through E to recruit at $<100 m^{-2}$ depending on larval mortality rate—even with all other factors optimized!

The “take home” message from these illustrations is the

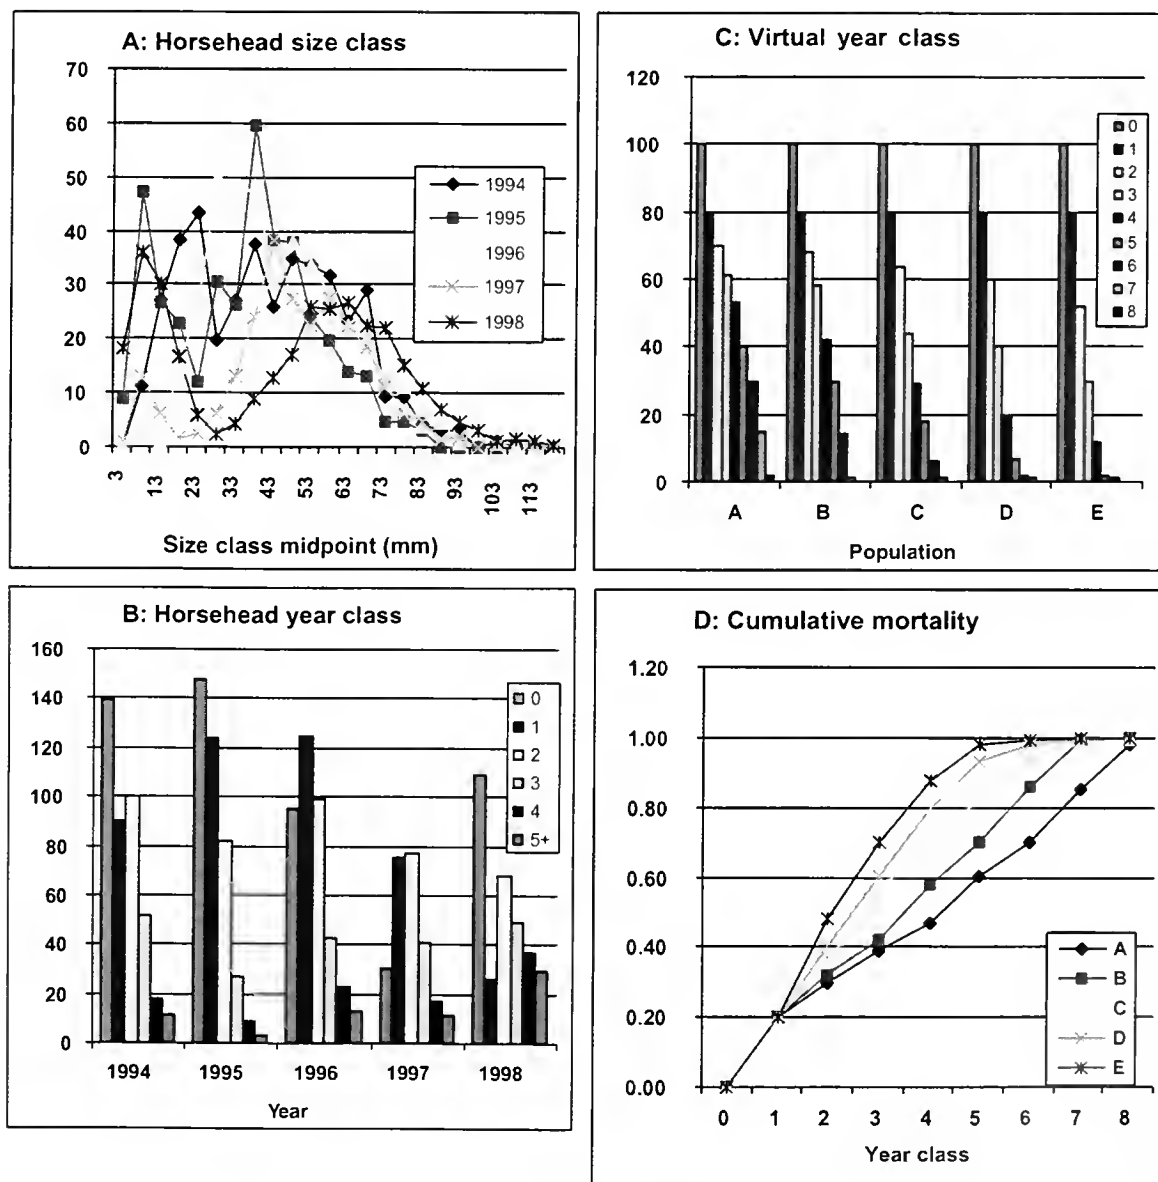

Figure 2. Continued on next page.

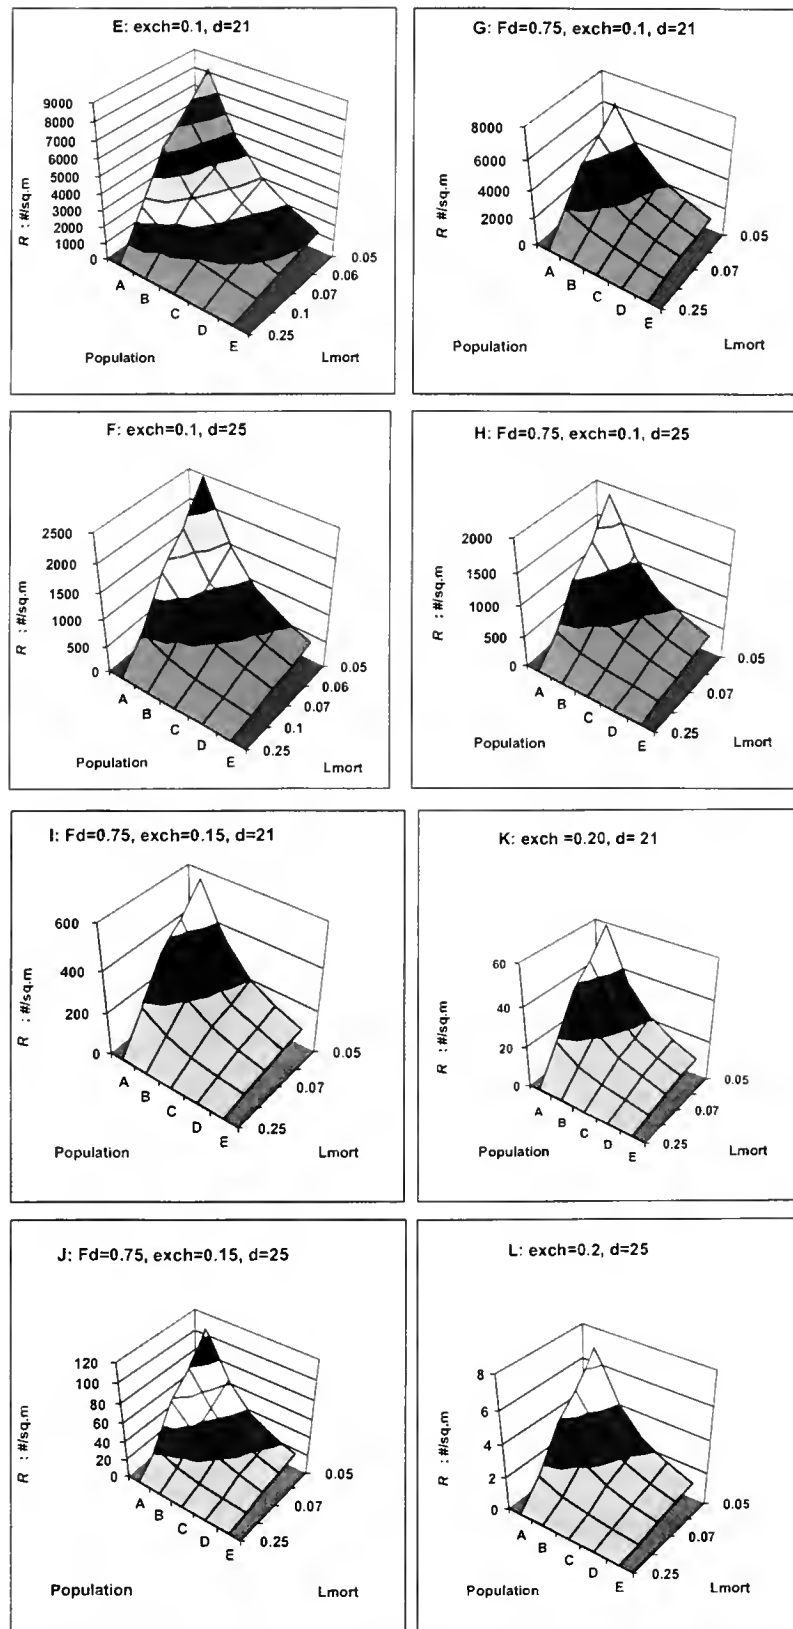

Figure 2. Estimation of recruitment, R , under various scenarios of initial population demographics, estuarine tidal exchange ($exch$), larval duration (d), and larval mortality rate (L_{mort}). See text for details. (A) Demographic data from Horsehead Reef 1994–1998. (B) Data recast as age class. (C) Virtual population demography used in simulations as a series of populations (A–E inclusive) generated by gradually increasing age-specific mortality (illustrated in D). very nonlinear response to various combinations of tidal exchange, reduced fecundity, and larval duration as we move away from an optimal combination. Even the most stable population structure, A in Figure 2C, may produce marginal recruitment scenarios despite the optimization of shell and substrate competition (P_{sub} and P_{foul}) and with no consideration of greater impact of postsettlement mortality. In a large number of slightly less than optimal scenarios, a population approaching current "disease tolerant" strains under sustained disease pressure—E in Figure 2C—is prone to inadequate recruitment. In other words, disease tolerance alone will not get us to where we want to be in current restoration work. In practical terms, failure to effect restoration in the optimal location will result in failure in recruitment. Optimal location is a product of species traits that are arguably very conservative because of the evolution of the species [again see McEdwards (1991), Hall & Wake (1999)] in combination with circulation patterns of the host estuary—a unique feature. Critical oyster traits in this mix include, but are not limited to, adult egg production, a trait for which we have not actively selected in breeding programs to date, and larval feeding ability and swimming behavior in turbid conditions. Fecundity is critical to driving the simulation as shown, yet we know essentially nothing of size–fecundity relationships under challenging conditions in which we are attempting restoration. Both larval traits are arguably very highly conserved because of structural limitations in the velar structure and the clear selective pressure over time for larval forms that recruit in optimal rather than sub-optimal environments. Turbid conditions can be viewed as transitions in the ephemeral lives of estuaries on a geological time frame, signals for oyster populations to move as they have done over periods of sea level rise. Larvae have no reason to evolve to survive in regions doomed to local extinction by rapidly changing environments—their conserved feeding abilities and behavioral strategies have served them more than adequately without such abilities. Restoration efforts thus match a suite of larval traits with conditions that we strongly suspect are very far from optimal, yet we often proceed in the absence of knowledge as to how debilitating this mismatch may be to the desired end point. These troubling scenarios, well founded in both our current understanding of the evolution of complex life history and simple numerical simulations of recruitment processes in virtual populations under near optimized conditions, are cause for concern. Without quantification of the individual data needs and their holistic synthesis in a practical model, the options for adaptive management of long-term, very high dollar cost restoration efforts, are limited, indeed sobering and probably doomed to mediocrity.

ARE DATA NEEDS FOR HOLISTIC SYSTEM LEVEL RESTORATION ACHIEVABLE?

The pressing need is to build a comprehensive model of oyster reproductive biology, larval growth and behavior, in response to estuarine circulation as a holistic adaptive management tool to guide restoration efforts for *Crassostrea virginica* in "low-salinity sanctuary" zones of the Chesapeake Bay. Fortunately, the tools for this are in place.

Disease-tolerant oyster strains have been, and continue to be developed under a multi-institutional, mid-Atlantic effort supported by the National Oceanic and Atmospheric Administration's Oyster Disease Research Program in a program whose heritage can be traced back to the pioneering efforts of Harold Haskin in Delaware Bay following the early impacts of MSX. Current hatchery

protocols allow for the description of the quantitative relationship between oyster size and fecundity at varying salinities typical of restoration sites. Whereas optimal salinity from literature studies may target a 15–25 ppt range, values in the 6–12 ppt range better reflect the upriver sanctuary regions of much of the Virginia sub-estuaries where extant oyster populations survive at the edge of endemic disease challenge. Culture of larvae from these fecundity studies at prevailing salinity under optimal and suboptimal (increased turbidity) conditions would greatly increase the confidence in growth and mortality rates as applied in the earlier simulation exercise.

The description of feeding under the combined stresses of low salinity and high turbidity remain poorly examined, although are eminently tractable in experimental systems. Mann, Kingsley-Smith, and Southworth (unpublished data) have used monocultured phytoplankton food and parallel cultures from the same source with additions of montmorillonite clay to simulate turbidity from upstream locations approaching the turbidity maximum; however, the challenge remains to use a complete characterization of low-salinity turbidity zones in terms of light penetration, particle concentration, and particle size in such experiments. The turbidity component of such data is emerging from separate studies of water quality on temporal and spatial variability in water column conditions in selected regions in the Virginia tributaries as these promote or limit submerged aquatic vegetation growth (Moore et al. 1996, Moore et al. 1997, Moore & Wetzel 2000). Sophisticated instrumentation for real-time, continuous generation of such data in transect mode is available. A critical issue yet to be examined is the changing quality of available food in these drainage conduits for disturbed watersheds. In such regions, increased run-off in conjunction with agricultural- and sewage-based nutrient enrichment serve to alter the balance of C:N:P:Si and thus the composition of the phytoplankton community. Concern over eutrophication typically focuses on mass rather than compositional issues, but it is inevitable that food quality will also change. Given the evolutionary history of larval forms, such changes can only be viewed as negative with concomitant prospects for recruitment to the benthos.

The contribution of oyster larval swimming behavior to larval retention has been extensively debated. Discussions of the additive, compounded, or antagonistic effects of these stimuli on larval swimming are offered in a series of papers by Mann (1985, 1986a, 1986b, 1988a, 1988b) and Baker and Mann (1997, 1998, 2003). Examination of swimming response to oriented stimuli are equally tractable in both laboratory and field settings using established protocols (Mann & Wolf 1983, Mann 1988a, McCarthy 1990, Mann et al. 1991, Baker & Mann 2003). The question in the current context is which (singular or plural) of these stimuli [light as intensity and/or wavelength, temperature, salinity (= density), pressure, and gravity] is relevant to the low-salinity location and is liable to modification by local increases in turbidity? Remember that we are seeking modification of a conserved behavioral response that has served the oyster larval form during the millennia, a modification particular to this recent (in geological time) temporal aberration from the optimum. In shallow upstream situations, we argue that the oriented responses to pressure are highly conserved [see the arguments for *Ostrea edulis* by Cragg & Gruffydd (1975)] and that stratification in both temperature and salinity will be minimal. This is substantiated for shallow locations in the James, Piankatank, and Great Wicomico Rivers from extensive summer survey data for the period 1985–2003 (reports available

on the VIMS Molluscan Ecology website at www.vims.edu/mollusc. We present the opinion that response to light in terms of both intensity and spectral composition as that most liable to modification, with resultant changes in larval depth stratification, and hence passive lateral dispersal; however, experimental verification of this stance must await future work.

The advancement of computer central processing power and code have fueled the development of three-dimensional transport models with biologically relevant cell sizes (with respect to known habitat heterogeneity) and time steps that have particle tracking capability in specific locations in the Chesapeake Bay. These models have been used in applications varying from water quality and sediment transport simulations to modeling circulation impacts of channel or shoreline alteration (such as in maintenance dredging or port construction), to modeling dispersal patterns of crab species with contrasting larval development (Garrison 1997), and critical placement of hard clam sanctuaries in the York River (see simulations at <http://www.vims.edu/physical/WEB/York1.htm>). All major restoration programs should have within their goals the development of such models as guidance tools.

Exploratory simulations can be run for virtual restoration scenarios driven by initial egg production estimates based on the modifications to the function ($F_{tot} \times F_q \times F_c \times F_d \times F_r$) as dictated by the projected additions of disease-tolerant broodstock. In a practical sense, we need realistic values for the function $(1 - exch)^{2d}$ in various locations targeted for restoration in the Chesapeake Bay by the communal efforts of ACOE, VIMS, VMRC, and others. Historical observations on the role of the Piankatank and

Great Wicomico Rivers as trap-type estuaries (Andrews 1979) suggest this function to be small in both rivers. Indeed, both the Piankatank and Great Wicomico Rivers have successful histories of restoration activity (Southworth & Mann 1998, Luckenbach et al. 1999). The James River, the site of the only extant oyster fishery of any consequence in Virginia, is of historical context in terms of circulation (Pritchard 1953, Wood & Hargis 1971, Mann 1988a, Ruzecki & Hargis 1989) in that depth-related counter flows, gyre-like circulation in Hampton Roads, and tidally driven frontal systems all contribute to larval retention. These locations provide extensive historical data sets to blind test our simulations through hind casting. Iterative improvement of such simulations in turn provide for robust capability in forecasting mode and, ultimately, successful restoration of populations in the field. The challenge is simply to use this vast array of exciting tools in the task before us.

ACKNOWLEDGMENTS

This work was supported by NOAA Oyster Disease Research Program Grant No. NA26FL0385-01, NOAA Chesapeake Bay Stock Assessment Committee Grant No. NA66FU0487, and the NOAA Office of Sea Grant under Grant No. NA56RGO141. The assistance and discussions of our colleagues James A. Wesson, Melissa Southworth, Juliana M. Harding, Kenneth Moore, and Harry Wang are gratefully acknowledged. This manuscript is dedicated to our friends and colleagues Reinaldo Morales-Alamo and Kenneth S. Walker, both recently retired, in appreciation of their career contributions to the knowledge of oysters in the Chesapeake Bay.

ECOSYSTEM INFLUENCES OF NATURAL AND CULTIVATED POPULATIONS OF SUSPENSION-FEEDING BIVALVE MOLLUSCS: A REVIEW

ROGER I. E. NEWELL*

*Horn Point Laboratory, University of Maryland Center for Environmental Science,
Cambridge, Maryland 21613*

ABSTRACT Suspension-feeding bivalves serve to couple pelagic and benthic processes because they filter suspended particles from the water column and the undigested remains, ejected as mucus-bound feces and pseudofeces, sink to the sediment surface. This biodeposition can be extremely important in regulating water column processes where bivalves are abundant in coastal waters and in seasons when water temperatures are warm enough to promote active feeding. Bivalves under these conditions can exert “top-down” grazer control on phytoplankton and in the process reduce turbidity, thereby increasing the amount of light reaching the sediment surface. This has the effect of reducing the dominance of phytoplankton production and extending the depth to which ecologically important benthic plants, such as seagrasses and benthic microalgae, can grow. Nitrogen and phosphorus, excreted by the bivalves and regenerated from their biodeposits, are recycled back to the water column and support further phytoplankton production. In some situations, however, bivalves can also exert “bottom-up” nutrient control on phytoplankton production by changing nutrient regeneration processes within the sediment. Some of the N and P that was originally incorporated in phytoplankton, but was not digested by the bivalves, can become buried in the accumulating sediments. Where biodeposits are incorporated in aerobic surficial sediments that overlay deeper anaerobic sediments, microbially mediated, coupled nitrification–denitrification can permanently remove N from the sediments as N₂ gas. Consequently, natural and aquaculture-reared stocks of bivalves are potentially a useful supplement to watershed management activities intended to reduce phytoplankton production by curbing anthropogenic N and P inputs to eutrophied aquatic systems. Environmental conditions at bivalve aquaculture sites should be carefully monitored, however, because biodeposition at very high bivalve densities may be so intense that the resulting microbial respiration reduces the oxygen content of the surrounding sediments. Reduction in sediment oxygen content can inhibit coupled nitrification–denitrification, cause P to become unbound and released to the water column, and the resulting buildup of H₂S can be toxic to the benthos.

KEY WORDS: benthic–pelagic coupling, bivalves, denitrification, eutrophication, extractive aquaculture, nutrient cycling, nutrient enrichment, nutrient trading, suspension-feeders

INTRODUCTION

Coastal waters worldwide are increasingly enriched with nitrogen and phosphorus as a consequence of agricultural fertilizer run-off and sewage inputs from growing human populations along coastal margins (Malone 1992, Conley 1999, Cloern 2001). This anthropogenic nutrient overenrichment is causing fundamental changes in the patterns and magnitude of primary production, including enhanced phytoplankton production and blooms of both toxic and nontoxic microalgae (Shumway 1990, Cloern 2001). In locations where this enhanced phytoplankton production exceeds the demands of metazoan herbivores, the excess phytoplankton carbon is metabolized by bacteria and protists and is not efficiently transferred to higher trophic levels (Pomeroy & Wiebe 1993). These high levels of microheterotrophic respiration frequently generate hypoxic or anoxic conditions in estuarine bottom waters. For example, in Chesapeake Bay, USA, water beneath the pycnocline in the deepest channel becomes anoxic most summers when the level of bacterial respiration, supported by the carbon produced during the spring phytoplankton bloom, exceeds the rate of oxygen resupply from the surface (Kemp & Boynton 1992, Diaz & Rosenberg 1995). In an effort to curb phytoplankton production in Chesapeake Bay, actions have been taken throughout the watershed to control inputs of nutrients from point and non-point sources, such that there will be an overall reduction by 40% of controllable inputs from the maximum levels recorded (D’Elia et al. 1992).

Phytoplankton concentrations increase not only as a result of

enhanced nutrient inputs—the so called “bottom-up” influence—but similarly increase when there is a reduction in the abundance of grazer organisms that normally exert “top-down” control (Newell 1988, Dame 1996). Thus, in eutrophic waters, consumption of particulate organic matter (POM) by abundant stocks of bivalve suspension-feeders in shallow and well-oxygenated conditions will directly reduce the amount of POM remineralized by bacteria beneath the pycnocline where oxygen resupply is restricted. Verwey (1952) was the first to identify the important ecological role of bivalves that are often the dominant component of the macroinvertebrate community in many coastal ecosystems. He recognized that bivalves serve as key agents in benthic–pelagic coupling because they feed on seston and transfer undigested organic and inorganic material in their feces and pseudofeces to the sediment surface.

The diverse influences that populations of suspension-feeding bivalves exert on marine ecosystem processes have comprehensively been reviewed by Dame (1996). I review here only those aspects of bivalve suspension-feeding ecology that pertains to their ability to alter water quality in eutrophic temperate estuaries and that may change the environment in a manner that affects other species. It is likely that some of these ecosystem effects will be a linear function of bivalve density, even at the rather high population densities associated with aquaculture farms, unchecked growth of an exotic species, and so forth. Other effects may be positive at low and moderate population densities but these beneficial changes can be reduced or lost at extremely high densities, as could result from overintensive aquaculture. I do not discuss the important secondary benefits of natural and cultivated shellfish beds as habitat for many invertebrate and vertebrate species (Coen et al. 1999). There is little known about such habitat benefits that

*Corresponding author. Fax: +1-410-221-8490; E-mail: newell@hpl.umces.edu

may derive from bivalves commercially cultured in various holding gear (e.g., rack and bag culture, attached to suspended ropes, held in floating trays, and so forth). These aquaculture structures are likely to provide a surface for fouling growth that serves as a food source for many animals and to some extent provide the type of spatially complex habitat that is sought by many species of animals. More research is required to determine to what extent the extreme periodic disturbances associated with cultivation and harvest practices, especially those required for on-bottom culture of infaunal bivalves, positively or negatively affect the habitat (Simenstad & Fresh 1995).

BIVALVE FEEDING

Suspension-feeding bivalves clear seston particles greater than $\sim 3\text{-}\mu\text{m}$ diameter from the water column with high efficiency during times of the year when water temperatures are sufficient to promote activity (Bayne & Newell 1983, Bayne & Hawkins 1992). Captured particles are sorted on pallial organs prior to ingestion, with the less nutritious and excess particles being immediately rejected as pseudofeces (Newell & Jordan 1983, Newell & Langdon 1996, Ward et al. 1997). In some situations, pseudofeces, which have not been exposed to any type of digestive degradation, can account for as much as 80% to 90% of the total volume of filtered particulate material (Tenore & Dunstan 1973, Bayne & Hawkins 1992).

The feeding response of bivalves to changes in seston concentration varies considerably among species. Some species, such as the eastern oyster, *Crassostrea virginica*, and the blue mussel, *Mytilus edulis*, maintain relatively high clearance rates even when seston concentrations increase (Newell & Langdon 1996, Hawkins et al. 1998). By maximizing the number of particles captured and subjected to efficient preingestive sorting and selection processes, such species can maximize their ingestion of nutritious particles (Newell & Langdon 1996, Ward et al. 1997). The maintenance of high feeding rates appears to be an adaptation to living in estuarine systems that historically supported low concentrations of phytoplankton in relation to less nutritious detrital and mineral particles. Today, throughout the majority of the estuaries and coastal waters of North America and western Europe, phytoplankton production has increased due to anthropogenic nutrient enrichment (Cloern 2001). Therefore, once the bivalve's nutritional needs are satisfied, excess phytoplankton cells, in addition to less nutritious detrital and silt particles, are rejected in pseudofeces. In response to increasing seston concentrations, other species of suspension-feeding bivalves, such as cockles, clams, and scallops, mainly regulate their ingestion rates by reducing clearance rates and not so much by rejecting excess particles as pseudofeces (Hawkins et al. 1998, Grizzle et al. 2001). Consequently, the species of bivalves that can exert the greatest influence on benthic-pelagic coupling are those that maintain high clearance rates and reject large numbers of particles as pseudofeces.

Ingested material is subject to extracellular and intracellular digestion, and the remains are defecated within ~ 24 h. Bivalves digest and assimilate different sources of POM with efficiencies that can vary from $\sim 20\%$ to 90% (Bayne & Newell 1983, Kreeger & Newell 2001). This efficiency varies depending on how susceptible the particles are to enzymatic breakdown; for example, many chlorophyte algal species are poorly digested because of their characteristically thick cellulosic cell walls (Langdon & Newell 1996). Assimilation efficiencies of bivalve molluscs for some particles,

including phytoplankton, also varies seasonally (Kreeger & Newell 2001). This high variability in assimilation efficiency, together with the substantial amounts of POM in pseudofeces that is not even subject to digestion, means that large amounts of undigested particulate organic nitrogen (PON) and phosphorus are transferred to the sediment surface in feces and pseudofeces (collectively called biodeposits). Newell & Jordan (1983), working with eastern oysters fed on natural seston ranging in concentration from 5 to 20 mg L^{-1} , reported that $\sim 50\%$ of the PON cleared from the water column was assimilated, and the remainder was voided in biodeposits.

Of the N absorbed by bivalves from the ingested food, the majority is used for tissue growth and some is excreted as urine (70% of which is NH_4^+ , 0% to 13% urea, and 5% to 21% amino-N; Bayne et al. 1976, Bayne & Hawkins 1992). This excreta increases the water column dissolved nitrogen pool and hence can support new phytoplankton and microphytobenthos production (Kaspar et al. 1985, Asmus & Asmus 1991, Swanberg 1991). Feces and pseudofeces are voided from bivalves as mucus-bound aggregates; consequently, they have a faster sinking velocity than nonaggregated particles and settle at rates up to 40 times that of nonaggregated particles (Kautsky & Evans 1987, Widdows et al. 1998). In locations where bottom water currents are below the critical erosional bottom shear stress (Newell et al. 2005), the biodeposits undergo a de-watering process and gradually become incorporated into the sediments (Haven & Morales-Alamo 1966, Haven & Morales-Alamo 1968, Kaspar et al. 1985, Jaramillo et al. 1992, Widdows et al. 1998) leading to an increase in sediment nitrogen content (Kaspar et al. 1985, Kautsky & Evans 1987, Deslous-Paoli et al. 1992, Hatcher et al. 1994). It should be noted, however, that resuspension of biodeposits from intertidal or shallow-water bivalve populations (Dame et al. 1991a) is more likely than those from bivalves living in either deeper water or grown in suspended aquaculture systems, where the underlying sediments are isolated from frequent disturbance by wave action.

ECOSYSTEM EFFECTS OF BIVALVE FEEDING

The complex relationships among some benthic and pelagic processes that may be influenced by benthic bivalve suspension-feeders during seasons when they are actively feeding are summarized in a conceptual model (Fig. 1). This diagram highlights the role of bivalve feeding in removing both phytoplankton and inorganic particles from the water column, thereby reducing turbidity. The resulting increased light penetration to the sediment surface can potentially enhance the production of benthic plants, such as seagrasses and microphytobenthos (Newell & Koch 2004). Reductions in turbidity will be directly proportional to the abundance of bivalves. Consequently, there is likely to be a linear decline in turbidity as bivalve stocks increase in a location from low to high abundances (Fig. 2).

A number of studies [for a review, see Dame (1996)] have provided strong evidence that natural populations of suspension-feeding bivalves can exert top-down control on phytoplankton in coastal waters [e.g., ribbed mussels, *Geukensia demissa* (Dillwyn), in salt marshes of the eastern United States (Jordan & Valiela 1982) and blue mussels, *Mytilus edulis* (Linné), in the North Sea (Asmus & Asmus 1991, Dame et al. 1991)]. Similar ecosystem changes have been observed where bivalve stocks have been either experimentally increased to higher than normal abundances [e.g., blue mussels stocked in experimental enclosures (Riemann et al.

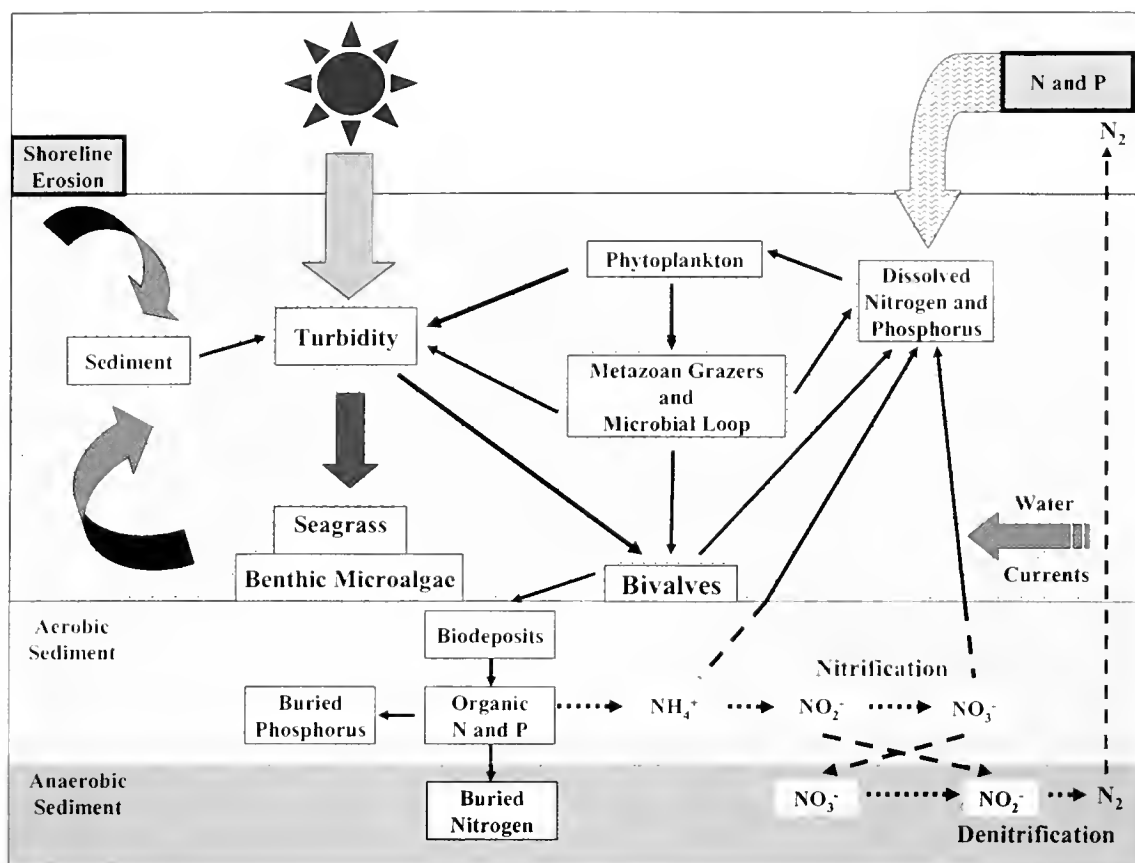

Figure 1. Conceptual diagram of the ecosystem effects of suspension-feeding bivalves in removing organic and inorganic particles from the water column and transferring undigested particulate material in their biodeposits to the sediment surface. Burial of P in aerobic sediments, and N throughout the sediment, leads to N and P removal from the water column. Within the aerobic sediment layers, the microbially mediated process of nitrification occurs, which when linked to denitrification within the underlying anaerobic sediment, leads to the further loss of N as N_2 gas. The growth of benthic microalgae (MPB) may be enhanced by increased light penetration to the sediment. The MPB can absorb regenerated nutrients, thereby out-competing phytoplankton. Solid lines indicate transfer of materials; dashed lines indicate diffusion of materials; dotted lines indicate microbially mediated reactions (adapted from Newell et al. 2002).

1988, Prins et al. 1995)] or as part of bivalve aquaculture, such as adjacent to rafts holding blue mussels in Spain (Tenore et al. 1982) and off-bottom aquaculture of Pacific oysters, *Crassostrea gigas*, in France (Souchu et al. 2001). The most dramatic ecosystem changes have been observed, however, in areas after the rapid population growth of an exotic species of bivalve. In San Francisco Bay, California, for example, phytoplankton has been shown to be controlled by non-native bivalves, including *Tapes japonica* and *Musculus senhousia* (Cloern 1982, Officer et al. 1982), and *Potamocorbula* spp. (Carlton et al. 1990). In freshwater systems of North America, non-native zebra mussels, *Dreissena polymorpha*, have increased to such an abundance that they have greatly reduced turbidities by consuming high levels of phytoplankton (MacIsaac et al. 1999, Strayer et al. 1999).

Seagrasses were once a very abundant ecotype in many locations worldwide, where they provided spatially heterogeneous habitat used by sessile and mobile fauna (Orth et al. 1984). These beds of submerged aquatic vegetation (SAV) have declined in many locations due to the adverse effects of anthropogenic nutrient enrichment (Twilley et al. 1985, Cloern 2001). Enhanced turbidity associated with high phytoplankton biomass can reduce the photosynthetically active radiation (PAR) to below the level required to enable SAV to grow (Twilley et al. 1985, Taylor et al. 1995).

Bivalves, by filtering phytoplankton and other particles from the water column, may increase PAR penetration to the point where SAV beds can become reestablished. The importance of suspension-feeding bivalves in promoting the reestablishment and growth of SAV has been demonstrated in the Potomac River, MD, USA. There, freshwater asiatic clams, *Corbicula fluminea*, reduced phytoplankton stocks (Cohen et al. 1984) and helped SAV to once again become dominant primary producers in freshwater locations (Phelps 1994). After a crash in the asiatic clam population of the Potomac River, there was a concomitant decline in SAV abundance (Phelps 1994). Increased water clarity will also promote the growth of microphytobenthos (MPB). These benthic algae are an important food source for both sessile and mobile benthic herbivorous meiofauna and macrofauna (Miller et al. 1996) that, in turn, are eaten by many carnivorous fish. Consequently, an abundant MPB community can support higher trophic levels.

Two modeling exercises support the idea that bivalve suspension-feeders can improve water clarity to the point that production of benthic plants is enhanced. Ulanowicz and Tuttle (1992) used an ecosystem model to predict that an important consequence of an increase in eastern oyster stocks in Chesapeake Bay would be to increase light penetration to bottom sediments to such an extent that MPB production would be greatly enhanced. Newell and Koch

Figure 2. Conceptual figure illustrating how increasing abundances of bivalves feeding on phytoplankton and inorganic particles reduce water column turbidity in eutrophic coastal waters. At high bivalve abundances, this may lead to intra- and interspecific competition for phytoplankton with other suspension-feeding herbivores. Biodeposits, containing undigested POM, are deposited to the sediment surface where they are microbially metabolized, thereby affecting sediment oxygen content. In locations where there is either extremely heavy biodeposition or little water flow and mixing, sediment oxygen content may decline, thereby reducing coupled nitrification-denitrification.

(2004) developed a numerical model to simulate the interaction between wave-induced sediment resuspension, bivalve filtration, and seagrass growth. This model, which is parameterized based on direct measurements of eastern oyster filtration and seagrass wave dampening effects, shows that the presence of eastern oysters can reduce suspended sediment concentrations by nearly an order of magnitude. This resulted in an increase in water clarity and, hence, the depth to which seagrasses could grow. It should be noted, however, that in coastal waters and tidally flushed estuaries, the exchange of suspended particles from adjacent waters means that the localized enhancement of bivalve stocks may not reduce turbidities sufficiently to permit seagrasses to grow.

A potential adverse effect of an increase in PAR at the sediment surface is that macroalgae may become established, rather than a more normal flora of seagrasses and MPB. Some types of macroalgae (e.g., *Ulva* spp., *Enteromorpha* spp., and *Cladophora* spp.) flourish in locations that have elevated levels of inorganic nutrients and relatively low irradiances (from 18 to 175 $\mu\text{mol m}^{-2}\text{s}^{-1}$), and under such conditions can out-compete other macroalgae (Peckol & Rivers 1995, Taylor et al. 2001). In some locations, these nuisance species grow so profusely that they restrict water flow and cause sediment hypoxia when they decay (Peckol & Rivers 1995, Raffaelli et al. 1998).

INFLUENCE OF EUTROPHICATION ON BIVALVE POPULATIONS

It is conceivable that increased phytoplankton biomass associated with nutrient enrichment may be beneficial to bivalve suspension-feeders. However, it is now recognized that anthropogenic inputs of N and P alter the ratio of these inorganic nutrients from

the typical Redfield ratio of 16:1 (Malone 1992, Conley 1999, Cloern 2001). Although subject to substantial variation, N:P ratios of agricultural run-off are of the order 50:1 to 70:1, whereas sewage input is closer to 10:1. The optimal ratio of N:P for algal growth is species specific, so changes in the N:P ratio alters the competitive interaction between phytoplankton species (Rhee 1978). For example, Terry (1982) demonstrated that *Pavlova lutheri*, which is considered a nutritious species for bivalves, has a high rate of P uptake and storage, but NO_3^- uptake is inhibited by increased amounts of P in the water. Consequently, a low N:P ratio might not stimulate the growth of *P. lutheri*, hence causing it to be out-competed by less nutritious species in which NO_3^- uptake is unaffected by P concentrations.

In coastal waters subject to anthropogenic nutrient loading, dissolved silicate frequently becomes depleted in relation to N and P, thereby leading to a reduction in the proportion of total primary production contributed by diatoms (Conley et al. 1993). Diatom species are generally considered to be a highly nutritious class of microalgae, and many species have been shown to promote survival and growth of bivalves (Langdon & Newell 1996). In Chesapeake Bay after the crash of the spring diatom bloom, other less nutritionally valuable classes of phytoplankton, including cyanobacteria and dinoflagellates, become dominant possibly due to the lack of available silica (Malone 1992, Conley 1999, Cloern 2001).

In addition to the ratio of inorganic nutrients, the chemical form of a nutrient can have a profound effect on phytoplankton species composition. Ryther (1954) concluded that eastern oyster stocks in the South Shore Bays of Long Island, NY, were adversely affected in the 1950s by extensive blooms of picoplanktonic algae, including *Nannochloris atomus* and *Stichococcus* spp., that were stimulated by duck farm fecal effluent containing high levels of ammonia and uric acid. These picoplanktonic species displaced nanoplanktonic algae that are more nutritious for oysters, with the consequence that the overall food quality of the phytoplankton for eastern oysters was reduced. Currently within the same South Shore Bays there are periodic blooms of the harmful picoplankton *Aureococcus anophagefferens* that causes "brown tide" (Bricelj & Lonsdale 1997). Gobler et al. (2002) reported that this species has a competitive advantage over other phytoplankton species because it can metabolize the high ambient levels of dissolved organic nitrogen and carbon that today are derived from human rather than duck farm waste. *Aureococcus anophagefferens* is toxic to bivalves as it has been shown to reduce the feeding and growth of all life stages of many species of bivalves [reviewed by Bricelj & Lonsdale (1997)]. It is thought that such blooms of toxin-producing algae are increasing in distribution and frequency worldwide, and anthropogenic nutrient enrichment is a likely causal factor (Shumway 1990, Cloern 2001). Even if the algal toxins do not adversely affect the benthic suspension-feeders themselves, they can be bioaccumulated in commercially valuable shellfish to levels that are unsafe for human consumption (Shumway 1990).

INFLUENCE OF BIVALVES ON PHYTOPLANKTON

As summarized above, suspension-feeding bivalves can serve to improve water quality in eutrophic estuaries by exerting top-down control on phytoplankton populations. In waters with substantial rates of bivalve grazing, however, larger nanoplankton cells will be preferentially removed in comparison with smaller (<3- μm diameter) picoplankton species that are retained less efficiently on the gill of most bivalve species. Furthermore, it appears

as if the growth of picoplankton compared with nanoplankton species is favored by warmer waters and changes in the relative abundance of inorganic and organic nitrogen (Malone 1992, Gobler et al. 2002). Hence, selective bivalve feeding, which is most intense during warmer months when bivalves are feeding actively, reinforces seasonal successional cycles in phytoplankton species composition, leading to the situation where picoplankton, including cyanobacteria, become relatively more abundant than larger species in areas with shellfish populations (Prins et al. 1998). Interestingly, Souchu et al. (2001) reported that high levels of bivalve aquaculture in a poorly flushed lagoon in the Mediterranean favored the production of picoplankton in all seasons except summer. Even though bivalve grazing was most intense in summer, high levels of DIN regenerated by the bivalves were sufficient to allow even the relatively slow growing nanoplankton to grow fast enough to overcome grazer control. Based on these observations, it is apparent that even though the exact seasonal changes in phytoplankton species composition are difficult to predict, bivalve grazing may possibly adversely affect food quality for other suspension-feeders.

In nutrient-enriched systems with consequent high levels of primary production, intra- and interspecific competition for food will likely be minimal at low and intermediate levels of bivalve abundance (Fig. 2). However, in systems that are either less productive, have limited water circulation, or have very high levels of bivalve biomass, intra- and interspecific competition for food may occur between natural and aquaculture stocks of bivalves. Interspecific food competition between high abundances of bivalves and zooplankton is also possible. Lam-Hoai et al. (1997) and Lam-Hoai and Rougier (2001) reported that in areas with shellfish aquaculture, there were appreciable differences in microzooplankton (cells 40- to 300- μm diameter) community structure compared with areas with no aquaculture farms. They ascribed these differences to microzooplankton being directly grazed by bivalves and also by the suspension-feeding invertebrates attached to the aquaculture structures. Bivalves may also out-compete zooplankton for phytoplankton because bivalves over-winter as adults and are able to start feeding when water temperatures reach the threshold necessary to promote an active metabolism. In contrast, temperate copepod species, which form a dominant component of the zooplankton, rely on a relatively small number of adults to survive over-winter and which can then feed and reproduce to rebuild the population. Copepod fecundity is directly related to food availability (White & Roman 1992), and consequently, if the majority of the phytoplankton is being consumed by adult bivalves, then copepod populations will diminish. This suggests that there is likely to be an exponential increase in interspecific competition for food as bivalve stocks increase in a location from low to high levels (Fig. 2).

NUTRIENT REGENERATION

In addition to the direct "top-down" control that bivalves can exert on phytoplankton stocks, they may also exert "bottom-up" control by changing rates and processes of nutrient regeneration (Fig. 1). Bivalves, by virtue of their high clearance rates, filter phytoplankton from large volumes of water. This has the effect of focusing nutrients that are then regenerated in the sediments around the population, hence increasing nutrient concentrations within that zone. Nonetheless, the total amount of nutrients regenerated directly by bivalve excretion and the microbial degradation

of their biodeposits cannot be any greater than if the phytoplankton was being degraded solely by pelagic organisms. Consequently, maximum phytoplankton standing stock supported by the nutrients regenerated through bivalve populations cannot exceed the level that can be sustained by ambient nutrients (Newell et al. 2005). This is in distinct contrast to fin-fish aquaculture, where new nutrients in the form of fish food are continually being added to the aquaculture site. Dissolved N and P excreted by fin-fish, together with that regenerated from their fecal waste and uneaten food, can stimulate excessive phytoplankton biomass. Furthermore, residual POM from the fin-fish food and feces settling to the sediment surface can cause sediment anoxia, thereby altering benthic community composition (Gowen & Bradbury 1987, Tsutsumi 1995).

Measured rates of NH_4^+ flux from natural bivalve communities (direct excretion plus regeneration from biodeposits in the sediments) can be substantial, ranging from ~ 1 to $5 \text{ mmol N m}^{-2} \text{ h}^{-1}$ (Dame et al. 1989, Asmus & Asmus 1991, Dame et al. 1991a, Dame et al. 1992), with rates being greater in summer than in winter months (Dame et al. 1992). The nitrogen released comes not only from ingested phytoplankton but also non-phytoplankton material, such as N-rich bacteria and flagellates (Asmus & Asmus 1991), that are readily captured by bivalves (Bayne & Hawkins 1992, Kreeger & Newell 2001). These high levels of NH_4^+ regeneration have been used by some investigators as evidence that bivalve populations may not be able to exert long-lasting top-down control on phytoplankton populations. Instead, it has been suggested that bivalves serve to recycle rapidly nutrients, thereby enhancing rates of primary production and phytoplankton biomass. Such conclusions are based either on direct measurements of phytoplankton production or production potentially supported by measured rates of N flux (e.g., Dame et al. 1984, Doering et al. 1986, Doering et al. 1987, Dame & Dankers 1988, Dame et al. 1989, Prins & Smaal 1990, Asmus & Asmus 1991, Dame et al. 1991b, Dame et al. 1992, Dame & Libes 1993, Yamamuro & Koike 1993, Nakamura & Kerciku 2000, Souchu et al. 2001).

What is frequently overlooked in such studies is that the burial of N and P and removal of N from the ecosystem via denitrification is enhanced by bivalve biodeposition (Newell et al. 2002, Newell et al. 2005). When bivalve biodeposits settle to the sediment surface, any remaining PON is subject to microbial degradation that can lead to some NH_4^+ being regenerated to the water column (Fig. 1). Some N that is not microbially metabolized can become buried in the accumulating sediments (Kaspar et al. 1985, Kautsky & Evans 1987, Deslous-Paoli et al. 1992, Hatcher et al. 1994). If the surficial sediments contain sufficient oxygen, then aerobic nitrifying bacteria can oxidize nitrogen compounds within the biodeposits to NO_2^- and NO_3^- . Some of this NO_2^- and NO_3^- diffuses out of the sediment and enters the water-column dissolved inorganic nitrogen (DIN) pool and some diffuses down into the underlying anaerobic sediments. Within the anaerobic sediments, denitrifying bacteria reduce the NO_2^- and NO_3^- to N_2 gas (Henriksen & Kemp 1988, Risgaard-Petersen et al. 1994). Absent nitrification, this gaseous N_2 is in a form unavailable to plankton and so it passes to the atmosphere without stimulating further primary production. Denitrification can only occur where there is a close juxtaposition between oxygenated conditions that support nitrifying bacteria and anaerobic conditions that support denitrifying bacteria (Kaspar et al. 1985, Kristensen 1988).

The influence of bivalve feeding and biodeposition on denitrification rates under natural field conditions have not yet been fully characterized. This is mainly due to the fact that a suitable method

for easily measuring denitrification in undisturbed sediments has only been recently devised (Cornwell et al. 1999). Newell et al. (2002) used this new method in a laboratory-based experimental system to study nitrogen regeneration from bivalve biodeposits under different scenarios typical of eutrophic estuaries. This involved using algal paste as an experimental analog of oyster biodeposits that was added to the surface of defaunated and homogenous natural sediments held in tubular cores. This was considered a realistic approach because bivalves only digest and absorb ~50% of the filtered particulate nitrogen, and hence the voided biodeposits contain a large proportion of residual PON (Newell & Jordan 1983). In these experiments, when PON was regenerated aerobically in the absence of light, 17% to 24% of the total PON added to the sediments was released as N_2 gas and hence would be unavailable to support further phytoplankton production. Newell et al. (2002) found that when the same amount of PON was degraded aerobically in incubations with sufficient light to sustain an active MPB community, little nitrogen was released to the water column and there was net N_2 fixation. It is widely recognized that an actively growing MPB community can limit nitrogen fluxes across the sediment-water interface (e.g., Sundbäck & Graneli 1988, Krom 1991, Rysgaard et al. 1995, Cerco & Seitzinger 1997, Sundbäck et al. 2000). Nitrogen fixation within MPB communities has previously been reported in many shallow-water environments when N requirements of benthic algal photosynthesis exceeds that supplied from the water column and regenerated from the sediment (Joye & Paerl 1994).

In addition to the role of MPB in intercepting DIN being regenerated from the sediments, the oxygen produced from MPB photosynthesis can alter sediment biogeochemistry. Some of this oxygen diffuses down into the sediment, thereby inhibiting the buildup of reduced inorganic compounds (Epping et al. 1999). In sediments subject to bivalve biodeposition, oxygen released by MPB can be used by bacteria in the micro-zone at the sediment-water interface to maintain nitrification, which is the critical precursor to denitrification (Sundbäck et al. 1991, Risgaard-Petersen et al. 1994, Rysgaard et al. 1994, An & Joye 2001). This pattern changes when MPB growth is high, such as may occur when turbidities are reduced by bivalve feeding in shallow-water locations. Under such circumstances, the demand for inorganic nutrients by MPB can be so great that they out-compete the nitrifying bacteria in the aerobic sediments for NH_4^+ . This results in a decline in the production of NO_2^- and NO_3^- , thereby curtailing coupled nitrification-denitrification (Risgaard-Petersen et al. 1994, Rysgaard et al. 1995, An & Joye 2001, Newell et al. 2002).

In one of the few field studies of the role of bivalves in nutrient cycling in which denitrification was evaluated, Kaspar et al. (1985) found appreciably higher denitrification in sediments underlying rope-cultured mussels than at reference sites. [Note that denitrification was measured in this study using the acetylene block technique that provides information on denitrification potential rather than absolute rates (Cornwell et al. 1999)]. Kaspar et al. (1985) discovered that biodeposition from aquacultured mussels not only increased PON in the sediment but also changed the benthic community from a diverse assemblage, including epibenthic species, to one composed solely of infaunal polychaetes that enhanced bioturbation and hence increased coupled nitrification-denitrification. Hatcher et al. (1994) reported enhanced sedimentation under mussel aquaculture ropes that caused an increase in N accumulation in the sediment, a shallowing of the Redox Potential Discontinuity layer, and enhanced the NH_4^+ efflux from the sediment compared

with adjacent control areas. Such changes in sediment biogeochemistry do not preclude the possibility that there was enhanced denitrification in the sediments. Rather, as Hatcher et al. (1994) state, they could not make any definitive statements concerning the influence of bivalve biodeposition on ecosystem nitrogen balance because they did not have the techniques available to measure denitrification.

Souchu et al. (2001) studied how bivalve aquaculture altered water column nutrient cycling in a poorly flushed lagoon in the Mediterranean. They reported that for all seasons, except when phytoplankton were growing most rapidly in summer, bivalve grazing controlled phytoplankton biomass. Consequently, for most of the year the regenerated NH_4^+ from the aquaculture farms was not used by phytoplankton for new production. Instead it became available to be oxidized to NO_3^- by pelagic nitrifying bacteria, hence explaining their observation of elevated NO_3^- in the water column within the shellfish aquaculture farms. It is likely that this NO_3^- will diffuse into the sediments where it will be subject to denitrification, hence leading to N removal from these coastal lagoons.

Although bivalves are clearly important mediators of N cycling, their role in P cycling is less clear. For example, some studies demonstrate that P regeneration from bivalve stocks does not increase (Dame et al. 1989, Dame et al. 1991) or increases by ~50% (Asmus & Asmus 1991, Souchu et al. 2001). The balance between binding and release of P from oyster biodeposits is highly dependent on sediment oxygenation and the development of a redox gradient within the sediments. In estuarine sediments, P fluxes are controlled by interfacial adsorption and desorption processes, often involving iron and sulfur cycling (Krom & Berner 1981). Iron oxides at the sediment-water interface are a diffusive barrier to P fluxes across the sediment-water interface. Under fully oxygenated conditions, any P remaining in the biodeposits will be buried in the accumulating sediments. If the depth of the oxygenated zone in the surficial sediments decreases, the P-adsorbing iron oxide surface area can be reduced to iron monosulfides, thereby allowing the release of sedimentary inorganic P (Boynton & Kemp 1985).

The ecosystem effects of an increase in bivalves on sediment nutrient regeneration, and hence on phytoplankton production, will vary depending on bivalve population density and the rate of mixing of oxygenated water down to the sediment surface. Excess biodeposition, especially in low water flow environments, has the potential to stimulate bacterial respiration to such an extent that sediments become anoxic, thereby inhibiting coupled nitrification-denitrification (Fig. 2) and causing sediment-bound P to be mobilized. Such local adverse effects can be ameliorated by moderate water currents or wave action that allows biodeposits to be spread across a larger bottom area and that mix oxygen from the surface to the bottom waters (Haven & Morales-Alamo 1968, Dame et al. 1991).

The adverse effects of sediment overenrichment by bivalve biodeposits have often been observed in sediments underlying bivalves in suspended raft culture. For example, Ito and Imai (1955) reported that intensive oyster aquaculture resulted in underlying sediments becoming anoxic, and these effects appeared cumulative because the longer oysters were cultivated in a location, the more frequently sediment anoxia occurred. Such reductions in sediment oxygen content will reduce rates of bacterially mediated nitrification and increase the proportion of N released as NH_4^+ . When sediments become completely anoxic, the buildup of H_2S can kill

the aerobic nitrifying bacterial community. Consequently, even if aerobic conditions in the surface sediments are restored, nitrification will only recommence following the regeneration of the nitrifying bacterial community (Henriksen & Kemp 1988, Sloth et al. 1995). Similarly, sediments underlying intensive mussel raft aquaculture in a Spanish Ria exhibited rates of sulfate reduction, indicative of anaerobic microbial processes, that were 63% greater than in sediments outside the raft area (Tenore et al. 1982). Tuttle and Jonas (1992) also observed elevated amounts of microbially labile organic matter in surficial sediments beneath eastern oysters grown in floats in Chesapeake Bay. This led to about a 4-fold increase in sulfate reduction rates, although this increase was short-lived and confined to sediments in the immediate vicinity of the floats. These findings suggest that extremely dense bivalve communities can adversely affect sediment microbial processes by shifting them from aerobic to anaerobic metabolism as a result of increased POM loading (Fig. 2).

The development of anoxic sediments associated with intensive bivalve aquaculture can increase hydrogen sulfide to levels that are toxic to benthic animals (Diaz & Rosenberg 1995). For example, Dinét et al. (1990) studied bivalve aquaculture sites and observed that as biodeposition by *Crassostrea gigas* and *Mytilus edulis* increased, there was a commensurate decline in meiofaunal populations associated with sediment anoxia and elevated NH_4^+ in sediment pore water. Declines have also been observed (Tenore et al. 1982, Rodhouse & Roden 1987) in the abundance and species diversity of the burrowing and deposit-feeding macrobenthic organisms (bioturbators) that actively mix surficial sediments as a result of their feeding and burrow irrigation activity. Bioturbation serves to increase the surface area to volume ratio of the oxic-anoxic sediment interface both by forming anoxic microenvironments within the upper aerobic zone and by driving the redox potential discontinuity deeper into the sediments (Kristensen 1988). In this spatially complex interface between aerobic and anaerobic zones, denitrification rates are enhanced compared with sediments without bioturbators (Kaspar et al. 1985, Henriksen & Kemp 1988, Kristensen 1988, Pelegri et al. 1994).

Dense assemblages of bivalves do not always cause adverse changes in benthic community structure. For example, Dittmann (1990) reported that biodeposition from beds of blue mussels leads to an enhanced and more diverse benthic invertebrate assemblage that will promote bioturbation. In addition, POM remaining in biodeposits provides a major source of food to benthic meio- and macrofauna and serves as a food resource for secondary consumers. Grant et al. (1995) found relatively minor changes in macrobenthic biomass and diversity associated with biodeposition from suspended mussel culture. In contrast, Kaspar et al. (1985) found that the benthic community underlying rope-cultured mussels changed from one with a diverse species composition to one composed solely of infaunal polychaetes. As noted earlier, however, this increase in bioturbating polychaetes was responsible for enhancing the coupled nitrification-denitrification found in the aquaculture sediments compared with the control sediments.

THE POSSIBLE USE OF BIVALVES IN EXTRACTIVE AQUACULTURE

Current management strategies for curtailing the adverse effects of eutrophication in coastal waters depend on upgrading sewage treatment facilities, reducing agricultural run-off, and control-

ling atmospheric inputs (D'Elia et al. 1992). It is now recognized that a possible supplement to such nutrient controls is "extractive aquaculture" in which macroalgae are grown both for their biomass and the concomitant removal of the nutrients from that impaired water body (Chopin et al. 2001). The harvested biomass can be used either for food (e.g., the food additive carrageenan and *Porphyra* spp. used to make "nori") or as agricultural compost for fertilizer and biogas production (Gao & McKinley 1994).

Another heretofore not widely recognized form of extractive aquaculture is the growth of suspension-feeding bivalves. On a dry-weight basis, eastern oyster tissue and shell contains nitrogen (~7% and ~0.3%, respectively) and phosphorus (~0.8% and ~0.1%, respectively) (Galtsoff 1964; Newell, unpublished data) that is removed from the ecosystem at harvest. For example, a market-size eastern oyster of shell length 7.6 cm has a shell that weighs ~150 g and ~1 g dry tissue and which combined removes a total of 0.52 g N and 0.16 g P at harvest. Much of this N and P is in the relatively large shell and so when species with lighter shells, such as blue mussels, are harvested, less N and P will be removed.

In addition to the direct removal of N and P by harvesting, microbially mediated denitrification of PON transferred to the sediment surface in bivalve biodeposits has the beneficial effect of permanently removing N in the form of N_2 gas from the ecosystem. Burial of residual N and P from bivalve biodeposits in sediments also enhances nutrient removal from the water column. Consequently, suspension-feeding bivalves potentially offer this additional mechanism for N and P removal compared with extractive aquaculture of algae. Newell et al. (2005) estimated that the biodeposition activity of an adult eastern oyster (shell height 7.6 cm; ~1 g dry tissue weight) feeding under natural conditions in the Choptank River, a mesohaline tributary to Chesapeake Bay, caused 0.27 g P to be buried and 0.75 g N to be buried and denitrified annually. These estimates did not take into account the reduced levels of N and P removal during the time it takes oysters to grow from juvenile to adult size nor the enhanced levels of N and P removal as oysters grow larger than 7.6 cm.

One of the reasons for the increasing interest in extractive aquaculture is the possibility of a nutrient trading system being implemented in coastal waters, such as Chesapeake Bay (www.chesapeakebay.net/trading.htm). Nutrient trading schemes allow industry and municipal waste-water treatment facilities to purchase at market value extra nutrient removal capacity from others on the same receiving water body, rather than directly reducing their own nutrient inputs. This is becoming an important issue in the United States, where the Environmental Protection Agency is mandated by the Clean Water Act to improve water quality. One mechanism devised to help reduce phytoplankton production and thereby enhance water quality is the total maximum daily load (TMDL), which is the maximum daily amount of nutrients allowed to be discharged into a water body from all sources (www.epa.gov/waterscience/standards/nutsi.html). Nutrient trading will allow aquaculturists, who can document the amount of N and P removed by their farms, to be paid by those industries that find it less expensive to purchase nutrient removal rather than upgrade their own facilities to meet the TMDL. The use of extractive animal and plant aquaculture is actually a unique solution to helping attain these water-quality standards because it offers the only opportunity to reduce nutrients once they have entered a receiving body of water. This may be especially important in ameliorating the effects

of non-point source inputs that are the most difficult to regulate and control.

Aquaculture farms will have to undertake some procedures beyond those required for successful shellfish production to obtain remuneration for the amounts of N and P removed beyond those incorporated in bivalve tissue and shell. Such changes are necessary because sediment nutrient regeneration is extremely dependent on how the aquaculture facility is operated, including the species of bivalve being cultivated and the stocking densities. Furthermore, seasonal and physical characteristics of the aquaculture site, such as sediment porosity, water flow, abundance of bioturbators, and so forth, can directly and indirectly influence sediment biogeochemical processes. Consequently, any financial gain associated with nutrient trading will have to be balanced against possible increased operating costs associated with obtaining the targeted rates of nutrient removal.

The maximum top-down control on phytoplankton and enhancement of N and P removal only comes from species of bivalves, such as oysters, that maintain high clearance rates even when seston concentrations increase. Other species, such as hard clams, because of their comparatively low clearance rates (Grizzle et al. 2001, Newell & Koch 2004), have less influence on benthic pelagic coupling. In eutrophic conditions, the most active suspension-feeders will reject large amounts of phytoplankton as part of their copious pseudofeces that are then transferred to the sediment surface. These receiving sediments must always remain fully oxygenated because microbially mediated nitrification only occurs under aerobic conditions, and this is the crucial precursor to denitrification in the underlying anaerobic sediments. Similarly, in fully oxygenated sediments, but not anaerobic sediments, phosphorus can become bound to iron and remain buried in the accumulating sediments. Therefore, bivalve stocking densities must be constrained to prevent local overenrichment of the sediments by the biodeposits that can lead to such intense microbial activity that even the surface sediment becomes anoxic (Fig. 2). Ideally, bivalves should be cultivated in locations with moderate current flow because the continual supply of oxygenated water reduces the likelihood of bottom sediments becoming anaerobic. Water currents also cause the biodeposits to be distributed across a larger bottom area (Haven & Morales-Alamo 1968), further reducing the likelihood that the surface receiving sediments will become anoxic. Water flow also increases seston flux through the aquaculture site, thereby ensuring an adequate food supply to the bivalves (Wildish & Kristmanson 1997).

Because some of the ecological benefits associated with aquaculture of bivalve suspension-feeders are so dependent on having aerobic sediments, the degree of sediment oxygenation around the aquaculture site must be regularly monitored. This can be performed routinely by measuring the depth of the redox potential discontinuity (RPD), either in sediment cores collected in transparent acrylic plastic tubes (Grizzle & Penniman 1991) or by using a remotely operated camera system that directly photographs the sediment profile (O'Connor et al. 1989). If the depth of the RPD is found to be moving progressively shallower, it indicates that the dynamic balance between aerobic and anaerobic sediments is shifting toward less oxygenated sediment. In such a situation, remedial actions should be taken to maintain the aerobic conditions needed to sustain both nitrifying bacteria and the benthic bioturbator community. This might require the use of a paddle-wheel system to increase the rate of mixing of surface oxygenated water to the bottom. Alternatively, if off-bottom aquaculture systems are being

used, these could possibly be relocated until the normal depth of the RPD at the original site is restored.

The reduction in turbidity associated with bivalve feeding may be sufficient to increase PAR penetration to the sediment surface to a level that can sustain MPB production. Actively growing MPB absorb inorganic nutrients released from bivalve biodeposits at the sediment water interface and compete with the sediment microbial community for N remaining in the biodeposits. Consequently, in locations where sufficient PAR reaches the sediment surface to permit active MPB growth, bivalve biodeposition may not result in appreciable nitrogen removal via denitrification (Newell et al. 2002). Therefore, if enhanced denitrification is a desired ecosystem service, aquaculture stocks of bivalves should be cultivated in deeper locations where the biodeposits will be transferred to sediments beneath the euphotic zone.

In any nutrient trading scheme involving suspension-feeding bivalves, it will be relatively easy to account for N and P removed in shell and flesh based on the annual harvest levels. Unfortunately, the factors that govern the magnitude of N removal and P immobilization (Newell et al. 2005) that are by-products of rearing bivalves are too complex and variable to allow the use of fixed removal rates that can be applied across all shellfish aquaculture facilities. For example, seasonal and physical characteristics of the aquaculture site, such as sediment porosity, current flow, abundance of bioturbators, and so forth, can directly and indirectly influence sediment biogeochemical processes. The magnitude of these possible variations are illustrated in a study by Sundbäck et al. (2000) of two different grain size sediments. They reported that coupled nitrification–denitrification rates were about an order of magnitude higher annually in finer grain sediments with active bioturbators than in sediments of higher porosity and with a slightly lower biomass of bioturbators. Because of such complex interactions, aquaculturists participating in nutrient trading will have to document the actual N and P removal at the specific locations. Appropriate N and P flux measurements can be made in sediment cores collected seasonally from the aquaculture sites and adjacent control sites. For shallow-water sites, these incubations will have to be made both in darkness and in the light to account for the influence of MPB on sediment biogeochemistry. Membrane inlet mass spectrometry can be used to obtain precise measurements of denitrification rates in relation to the release into the water column of other forms of inorganic nitrogen (Cornwell et al. 1999, Newell et al. 2002). The accumulation and burial of N and P into the sediment can be measured in separate sediment cores. These measured N and P removal rates can then be used as the basis of deciding what level of remuneration may be obtained from nutrient trading.

ACKNOWLEDGMENTS

I am grateful to Dr. Jeff Cornwell and Dr. Tom Fisher for their scientific discussions. I would like to thank Ray Grizzle, Becky Holyoke, Carter Newell, and Bob Rheault for their reviews of an early draft of this manuscript. This research was supported with funding from Maryland Sea Grant (SA07528051-F) through NOAA award NA16RG2207. ABSTRACT Time series of fishery-dependent and fishery-independent data were used to parameterize a model of oyster population dynamics for Maryland's Chesapeake Bay. Model parameters are (1) fishing mortality, estimated from differences between predicted and reported landings scaled to a fishery-independent estimate of exploitation rate; (2) natural mortality, estimated from the ratio of dead to live oysters in fishery-independent surveys; (3) recruitment, estimated from annual changes in the market oyster stock and total mortality rates; and (4) carrying capacity, estimated from predicted densities of oysters in the absence of either exploitation or excess mortality from parasitic diseases, multiplied by charted areas of high-quality and marginal habitat. The model predicts continuing decline in population abundance and biomass in the absence of significant management intervention. Moderate decreases in fishing mortality, alone or in combination with increases in recruitment through stock enhancement, could reverse recent population trends, resulting in a larger population and improved harvests within 1–2 decades, even if currently high rates of natural mortality are sustained.

KEY WORDS: *Crassostrea virginica*, fishing mortality, models, natural mortality, oyster, population dynamics, recruitment

INTRODUCTION

In 2000, the inter-jurisdictional Chesapeake Bay Program (CBP) established a goal to increase the bay's population of native oysters (*Crassostrea virginica*) 10-fold by 2010 from a 1994 baseline. With colleagues, we developed a preliminary quantification of the oyster population in Maryland's portion of the bay, along with methods for tracking population trends and predicting annual landings with an index of relative biomass (Jordan et al. 2002). A logical next step was to examine the potential contributions of various management strategies toward meeting the 10-fold restoration goal. To this end, we used time series of fishery-dependent and fishery-independent data to parameterize a model of oyster population dynamics. The model projects long-term trends in the Maryland stock of market-sized oysters (≥ 76 mm in shell height) with variable rates of fishing mortality (F), natural mortality (M), and recruitment (R). The model is limited to market oysters, first for simplicity, second because the relationship between oysters < 76 mm in shell height (pre-recruits) and the market stock has been difficult to quantify (Jordan et al. 2002), and third, because the goals of the CBP and the state of Maryland include restoration of the oyster fishery, in addition to the population as a whole (Maryland Oyster Roundtable 1993, CBP 2002). Moreover, the standing stock of larger oysters is an important indicator of population viability, whether the objectives of the restoration program are ecological, economic, or both.

The model is stochastic, that is, for each of many iterations of the model within a simulation, F, M and R vary randomly, constrained by means and standard deviations observed from the monitoring time series or specified by the user. The principal outputs are projected annual means of market oyster stocks and landings. To estimate the uncertainty associated with the results, the model computes percentages of model iterations that achieve specified targets. Thus, a user could evaluate proposed management strategies on the basis of, for example, 90% probability of achieving a desired outcome. Although the CBP oyster restoration goal set 2010 as the year in which to achieve a 10-fold increase, we

extended simulations to 2020 to present longer-range views of population trends.

Environmental forcings (e.g., variations in temperature and salinity) are not included explicitly in the model, except in the separate baseline parameter values for three salinity zones. We assume that the effects of environmental variations have been captured in the standard deviations of the baseline model parameters. The time-series data spanned 16 y, from 1986 to 2001, capturing a range of warm, cool, wet, and dry periods, along with other variations in the environment.

The model was designed to evaluate long-term management strategies in response to the CBP 10-y goal, and does not accurately reproduce or project short-term (interannual) population trends. Year-to-year tactical management decisions would be better addressed by a model similar to that developed by Klinck et al. (2001) for Delaware Bay oysters. The CBP (2002) emphasis on sanctuaries (i.e., areas permanently closed to oyster harvest) is an example of a long-term strategy appropriate for the model described here. In Maryland, sanctuaries generally are stocked with seed oysters produced in hatcheries. Consistent with the CBP plan and recent practice, we modeled the sanctuary strategy as a 10% decrease in F (to approximately 10% of productive bottom closed to the fishery), combined with a 10% increase in R (approximating potential hatchery contributions), and projected this scenario over 20 y. Another example of a long-term management strategy is projecting the effects of reductions in F in the range of 10–40%, for which the model predicts that initial decreases in landings will be more than compensated by increases after a few years.

The CBP (2002) plan is concerned with selecting sites for restoration projects and how different areas of the bay should be managed to achieve the restoration goal. The models for three salinity zones should be helpful in these decisions, although an ideal model for these purposes would have much finer geographical resolution (e.g., individual oyster bars). The model reported here should be a step toward a more detailed, age-structured, geographically articulated model.

MATERIALS AND METHODS

Parameters of the model are instantaneous rates of natural mortality (M), fishing mortality (F), and recruitment (R), plus point estimates of carrying capacity (K , an upper bound on the stock of market oysters). The unit of measure is one Maryland bushel (~ 46 L) of oysters. The only boundary condition is an initial estimate of the market stock (in bushels), which can be derived from landings and relative biomass (as described below) for any year for which monitoring data are available (Jordan et al. 2002).

The primary sources of data for model parameterization were (1) Maryland fall dredge surveys of oyster bars (1985–2000), and (2) annual commercial oyster landings reported to the Maryland Department of Natural Resources. The fall dredge surveys provided annual estimates of natural mortality rates and relative biomass of market-sized oysters and are described elsewhere (Smith and Jordan 1993, Homer et al. 1996, Maryland DNR 2001, Jordan et al. 2002).

We developed an aggregated model for all of Maryland's Chesapeake Bay and also developed separate baseline parameter values for each of three zones based on salinity data from the fall oyster surveys (Fig. 1). Salinity zones were defined by averaging salinity measurements taken from 43 dredge survey sites in October or November 1990–2000, then assigning sites to categories: high, >14 ppt; medium, 12–14 ppt; and low, <12 ppt. We used two criteria to establish the salinity ranges: (1) including roughly equal numbers of sites in each category so that each would have sufficient data, and (2) gradients in recruitment and the impacts of the oyster parasites *Haplosporidium nelsoni* and *Perkinsus marinus* on oyster mortality. At salinity <12 ppt, *H. nelsoni* infections occur rarely, if ever; *P. marinus* infections, although chronic in this zone, are associated with low to moderate mortality rates; and recruitment rates of both small and market oysters are typically very low, except in areas where natural recruitment has been supplemented by transplanted seed oysters. In the medium-salinity zone, *H. nelsoni* epizootics are sporadic, occurring only in drought years, mortality associated with *P. marinus* is moderate to high, and recruitment is variable. In the high-salinity zone, *H. nelsoni* infections tend to be enzootic, mortality rates associated with *P. marinus* infections are consistently high, and recruitment, although variable, tends to be higher than in the lower salinity zones (Jordan 1995, Giesecker 2001).

The model assumes classic logistic population growth, with two enhancements. First, instead of a net rate of population change [r , as in Krebs (1994)], the model includes separate parameters for instantaneous rates of natural mortality (M), fishing mortality (F), and gross annual recruitment (R). Second, each parameter is input for each simulation in Monte Carlo fashion, as a random number from a log-normal distribution with mean and standard deviation computed from the time series of monitoring data.

Natural mortality (M) estimates were based on the ratio of articulated dead oyster shells ($D = \text{boxes}$) to the total of live and dead oysters ($L + D$) in each dredge sample: $M = -\log_e(D)/(L + D)$. Fishing mortality was estimated from the ratio of reported landings to landings predicted by log-log linear regression from a fishery-independent biomass index for market oysters: $F = -\log_e[0.53 (H/\hat{H})]$, where H = reported landings, \hat{H} = landings predicted from relative biomass of market oysters, and 0.53 is a scaling constant derived from a fishery-independent estimate of the proportion of the market stock landed during the 1990–1991 season (Smith and Jordan 1993). For that season, the ratio H/\hat{H} was

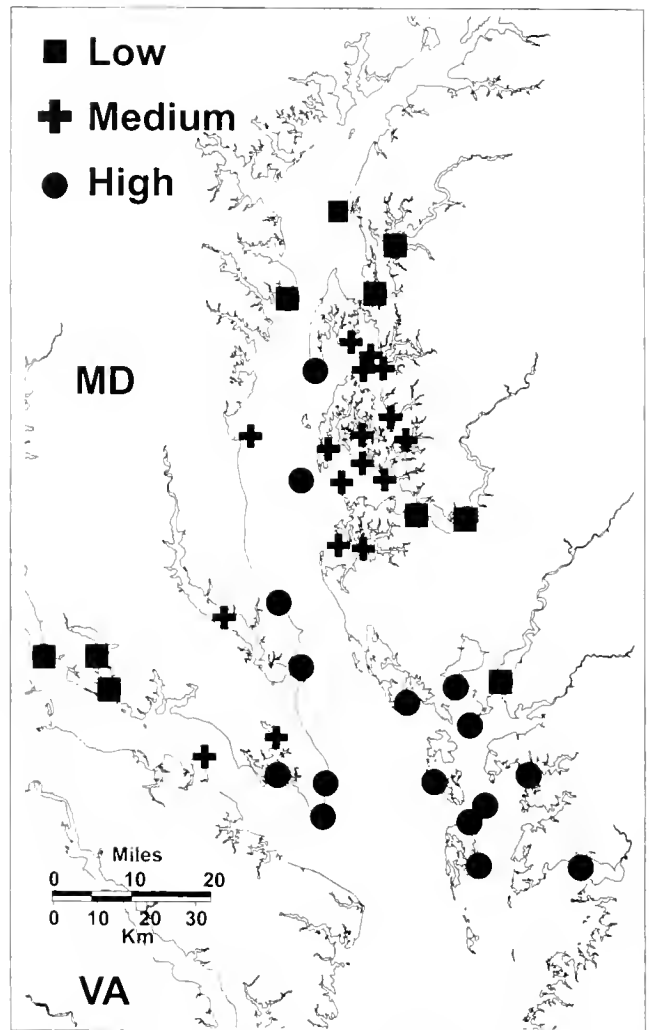

Figure 1. Northern Chesapeake Bay, showing 43 monitoring sites where oyster mortality, size frequency, and relative abundance data were collected.

approximately unity. These methods of estimating M and F were described and discussed by Jordan et al. (2002). Gross recruitment (R) was calculated as the instantaneous annual rate of change in the market oyster stock ($r = dS/dt$), plus total annual mortality ($Z = M + F$). The term dS/dt was estimated for a 1987–2001 time series by calculating stock size for each year as $S = (H)/(1 - e^{-r})$, where H is annual landings (R could not be computed for 1986, the first year of the monitoring time series).

We made four estimates of carrying capacity, one for each of the salinity zones, and one for the Maryland Chesapeake Bay as a whole. The Maryland Bay Bottom Survey (MBBS) of oyster bars was used to calculate acreage of cultch, mud with cultch, and sand with cultch bottom-type categories for each area. A variety of observations and surveys with patent tong grabs, divers, video, and acoustics indicated that only about 10% of these areas of nominal oyster habitat actually supported oyster populations (Smith et al. 2001, Maryland Department of Natural Resources, unpublished data). Even within productive areas, high densities of oysters (≥ 100 per m^2) occurred only in scattered patches. Thus, we assumed that at carrying capacity, 10% of cultch areas from the MBBS would support mean densities of 10 market oysters per m^2 .

and 10% of sand with cultch and mud with cultch areas would support mean densities of 3 market oysters per m².

We attempted to decompose Maryland-wide landings data to match the three salinity zones, but values of F estimated from landings and relative biomass by zone were extremely variable and in some cases unreasonable. Although landings were reported for discrete areas (fishing regions defined by the National Marine Fisheries Service) that could be matched with monitoring sites, landings reports reflected where the oysters were landed, not necessarily where they were caught. Moreover, some landings were reported from areas that could not be assigned to salinity zones based on monitoring data. Therefore, we used the bay-wide mean F, along with zone-specific estimates of M, R, and K, to initiate the salinity zone parameterizations.

The equation for simulating the market oyster population is: $S_t = (K/I + G \cdot e^{-(R-(M+F)t)})$, where S_t is the market oyster stock in year t , $G = (K - S_{t-1})/S_{t-1}$, S_{t-1} is the stock in the previous year, e is the base of natural logarithms, and the other parameters are as above. Values of any of the parameters can be specified to simulate particular scenarios. Standard deviations of F, M, and R also can be varied if desired. In all simulations reported here, the model was run for 20 y with 1000 iterations per year. Preliminary simulations with 5000 iterations produced results almost identical to those with 1000 iterations. Model output is processed to generate log-mean simulated stock size and landings for each year of the simulation. Simulated means of stock and landings are back-transformed to arithmetic values and graphed as time-series plots to portray expected trends. We established three reference points for evaluating bay-wide scenarios: (1) stock collapse, defined as market stock $< 0.1 \times 10^6$ bushels, (2) stock restoration, defined as a stock of at least 1.77×10^6 bushels (i.e., 10 times the stock estimate for the oyster restoration goal baseline year 1994), and (3) fishery restoration, defined as annual landings $\geq 2 \times 10^6$ bushels, consistent with the magnitude of landings sustained from the 1920s through the 1970s. The model calculates percentages of simulations within each scenario that indicate stock collapse or that achieve or exceed the fishery or stock restoration targets in the final year of simulation (2020), as measures of uncertainty for the bay-wide model. Lack of resolution in the landings data precluded fisheries targets for the salinity zone models, and starting stocks were so low in the medium- and high-salinity zones that stock restoration and stock collapse reference points would have had little meaning. We set a stock restoration reference for the low-salinity zone based on the CBP (2000) oyster restoration goal (i.e., 10 times the 1994 stock).

In the simulations reported here, we varied F and R to forecast the trends that would be expected under reasonable scenarios of management intervention (reductions in F and stock enhancement with hatchery-produced seed oysters). To simulate increased recruitment by means of stock enhancement, we made the following assumptions: hatchery production would not exceed about 2 to 3 $\times 10^8$ spat on shell per year; 30% survival of hatchery oysters from planting to market size; recruitment to the market stock 4 y after planting (Jordan et al. 2002); and 375 market oysters per bushel. These assumptions limited reasonable scenarios to a 10% increase in R. We also ran the models with baseline parameter values in both forecasting and hindcasting modes.

RESULTS

Maryland oyster landings varied by a factor of almost 20 from 1986 to 2001 (Table 1). Variations in F corresponded to annual

Year is the year in which October-March oyster landings were reported. F, M, and R are instantaneous rates of fishing mortality, natural mortality, and gross recruitment to the market stock, respectively. Landings data were rounded to the nearest 1000 bushels. R was not computable for 1986; $K = 16,964,000$ bushels of market-size oysters.

exploitation rates of 21–73% of the market stock. Natural mortality ranged from 10–60%, total mortality 43–81%, and gross recruitment 40–72%. Annual net rates of change in the market stock varied from –66% to +48%, with a majority (8 of 15 y) of negative values. The mean annual rate of change in the market stock from 1987 to 2001 was –10%. Annual landings and natural mortality (M) for the bay-wide model, along with computed values of K, F, R, and S, are listed in Table 1.

Because the monitoring data we used to establish salinity zones did not support full coverage of oyster habitat or reported landings, our estimates of bay-wide K and initial stock were greater than the sums of K and initial stocks for the three salinity zones. Mean baseline parameters, initial stocks, and K for the three salinity zones are listed in Table 2.

Means of 1000 runs of a bay-wide hindcast simulation using the baseline parameters reproduced the observed trends in stock and landings from 1986 to 2001, but not year-to-year variation

TABLE 2.
Model baseline parameters and initial stock estimates for three salinity zones.

Zone	Low	Medium	High
K	4221.8	3006.4	5034.8
Initial stock	231.9	488.9	39.4
F	0.714 (0.253)	0.714 (0.253)	0.714 (0.253)
M	0.165 (0.081)	0.428 (0.287)	0.719 (0.519)
R	0.739 (0.589)	1.1885 (1.046)	1.283 (2.105)

The units of K and initial stocks are bushels $\times 10^3$. Means of F (simulated) and M are from 1986 to 2000 (time series); the mean of R is from 1987 to 2000. Standard deviations are in parentheses.

(Fig. 2). Many individual iterations from this simulation generated patterns similar to the actual time series, but many others diverged widely. The two examples shown in Figure 3 illustrate the stochastic properties of the model. The single iteration of the model shown in the upper pane of Figure 3 generally matched the pattern and magnitude of reported landings, whereas the iteration shown in the lower pane of Figure 3 was an extreme deviation from the data.

Forward simulation with baseline parameter values in the bay-wide model indicated continuing declines in stock and landings through 2020. A reduction of fishing mortality to 0.9F (90% of baseline, or $F = 0.64$) moderated, but did not reverse these trends. Forward simulations produced a consistent pattern of long-term increases in stock and landings at 0.8F and lower (Fig. 4). Because of overlapping trends among the scenarios, projected landings can be seen more clearly in three dimensions (lower plot of Fig. 4). At 0.8F ($F = 0.57$), the model projected approximately linear increases in stock and landings, with modest reductions in landings below the 1.0F and 0.9F scenarios for the first few years. Initial reductions in landings were followed by increases in subsequent years. At 0.7F ($F = 0.50$), there were exponential increases in stock and landings, with the stock increasing by a factor of 5.5 and landings by 5-fold over 20 y. Early losses to the fishery were compensated within the first few years. Reducing F to 0.6F ($F = 0.43$) increased stock by more than 10-fold and landings by 9-fold. Greater reductions in F (50% or more) increased stock size more rapidly, but long-term landings were less than for the 0.6F scenario. Simulated long-term fishery yields were optimum at 0.6F ($F = 0.43$; Fig. 4).

Forty-three percent of bay-wide simulations with 1.0F predicted stock collapse to $<0.1 \times 10^6$ bushels (Fig. 5). Reducing F to

Figure 2. Mean market oyster stock and landings simulated from a hindcast of the bay-wide oyster model with baseline parameter values. Reported landings are shown on the lower plot; no model-independent estimates of stock size were available for comparison. Simulated annual means and reported annual landings were smoothed by polynomial spline interpolation.

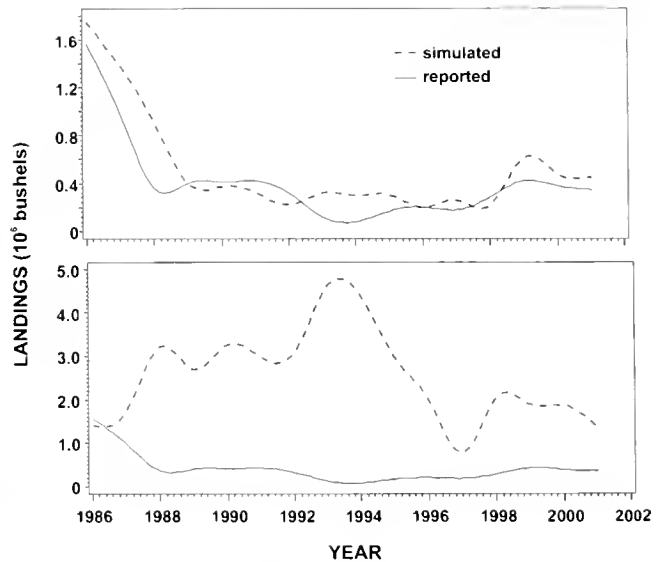

Figure 3. Simulated landings from two individual iterations of a hindcast of the bay-wide oyster model with baseline parameter values compared with reported landings; smoothed by polynomial spline interpolation.

0.6F or less virtually eliminated the probability of stock collapse. Stock restoration ($\geq 1.77 \times 10^6$ bushels) was achieved in 9.2% of simulations at 1.0F and 98% of simulations at 0.5F. The most stringent target, fishery restoration ($\geq 2 \times 10^6$ bushels projected landings), was achieved in 73% of simulations for 0.4F and 0.5F (right panel of Fig. 5); greater or smaller reductions in F indicated less likelihood of achieving the fishery restoration target.

Increasing the instantaneous rate of recruitment by 10% (1.1R, the maximum we thought to be achievable based on realistic levels of hatchery production), with F held at 1.0F, stabilized stock and

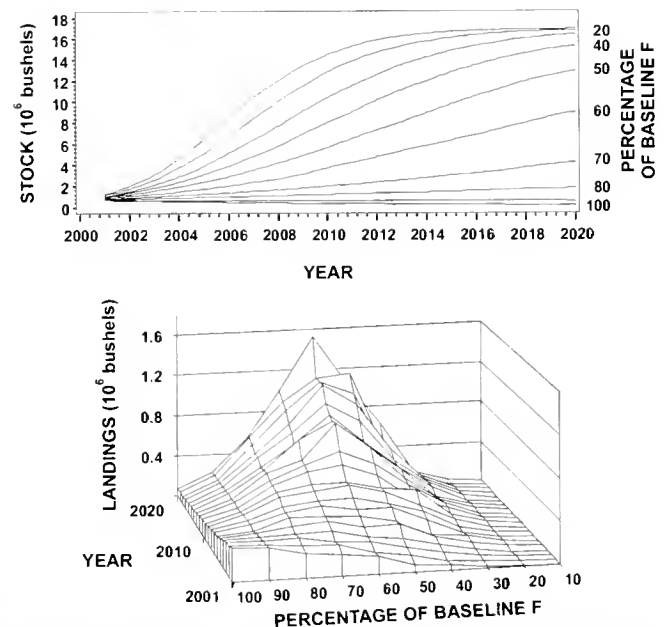

Figure 4. Annual mean simulated stock and landings for the bay-wide model at 10–100% of baseline F . Stock results were smoothed by polynomial spline interpolation; landings results were not smoothed.

Figure 5. Percentages of iterations of the bay-wide model at 10–100% of baseline F that indicated stock collapse (market stock $<0.1 \times 10^6$ bushels), stock restoration (market oyster stock $\geq 1.77 \times 10^6$ bushels), or fishery restoration (simulated landings $\geq 2 \times 10^6$ bushels). There were 1000 iterations for each value of F.

landings after an initial lag required for spat to reach market size (Fig. 6). A sanctuary scenario (i.e., coupling 1.1R with 0.9F) predicted approximately 3-fold increases in stock and landings within 20 y (Fig. 7). This scenario indicated a low likelihood (percentage of iterations) of stock collapse and moderate likelihoods of stock and fishery restoration (Fig. 8).

Hindcasts for all three salinity zones indicated exponential stock declines during the period 1986–2000 (Figs. 9–11). Simulated landings for the period were roughly consistent with reported landings for the low- and high-salinity zones, but less so for the medium-salinity zone. Forward simulations for the low-salinity zone indicated that F would have to be reduced to 0.6F to achieve increasing stocks of market oysters (Fig. 12). Long-term landings in this zone were stable at 0.8F and optimal at 0.6F (lower plot of Fig. 12). In the medium-salinity zone, stock increased at 0.7F and approached carrying capacity at 0.3F or less (Fig. 13). Long-term landings in the medium-salinity zone were stable at 0.9F and optimal at 0.7F (lower plot of Fig. 13). Moderate reductions in F had little or no effect on stock or landings in the high-salinity zone (Fig. 14). The model predicted substantially increasing stocks at 0.2F and 0.1F in this zone. Simulated long-term landings in the high-salinity zone attained maximum values at 0.1F, reaching 0.12×10^6 bushels by 2020, about 80% of 1986 landings from this zone. Simulations of a sanctuary strategy (0.9F, 1.1R) slowed, but did not reverse, stock declines in the low- and high-salinity zones.

Figure 6. Annual mean simulated stock and landings for the bay-wide model with a 10% increase in R above baseline. Reported annual landings are shown on the lower plot; all values were smoothed by polynomial spline interpolation.

Figure 7. Annual mean simulated stock and landings for the bay-wide model with a 10% increase in R and 10% decrease in F from baseline values; smoothed by polynomial spline interpolation.

In the medium-salinity zone, the sanctuary simulation predicted an increasing stock after an initial lag (Fig. 15).

The stock restoration target for the low-salinity zone was an increase from 0.16×10^6 to 1.6×10^6 bushels by 2020. A high likelihood of achieving this target required 0.4F or less (Fig. 16).

DISCUSSION

We have quantified the population dynamics of the Maryland harvestable oyster stock and simulated the long-term consequences

Figure 8. Percentages of 1000 iterations of the bay-wide model that indicated stock collapse (market stock $<0.1 \times 10^6$ bushels), stock restoration (market oyster stock $\geq 1.77 \times 10^6$ bushels), or fishery restoration (simulated landings $\geq 2 \times 10^6$ bushels) with 10% increase in R and 10% decrease in F from baseline values.

Annual reported landings are shown on the lower plot; no model-independent estimates of stock size were available for comparison. All values were smoothed by polynomial spline interpolation.

of several management scenarios for the stock as a whole, and also for three subpopulations segregated by salinity. The results indicate that there is potential for restoring the stock and the fishery to sustainable historical levels with reasonable management interventions. The following discussion elaborates on the uncertainties in

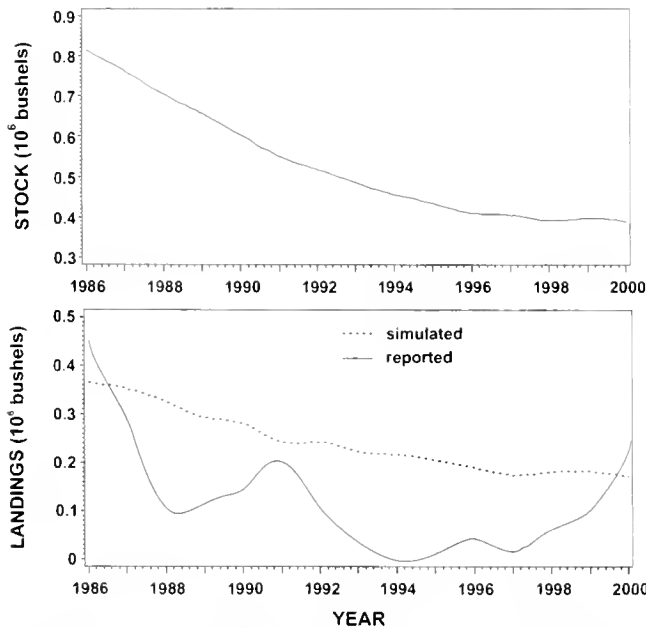

Figure 10. Annual means of simulated stock and landings from a hindcast of the medium-salinity (12–14 ppt) zone model. Annual reported landings are shown on the lower plot; no model-independent estimates of stock size were available for comparison. All values were smoothed by polynomial spline interpolation.

the data and assumptions that were used in the modeling process, examines management implications both prospectively and retrospectively, and offers recommendations for restoring sustainable oyster stocks in Maryland.

Uncertainties

There are at least three types of uncertainty associated with each of the model parameters: natural variation, measurement er-

ror, and inaccuracy (i.e., how closely sampling and estimation measure the true parameters). Natural variation is included in the model structure by allowing F, M, and R to vary according to observed temporal and spatial variation, and is applied to model results as shown in Figures 3 and 9. This variability permits a wide range of possible outcomes, for which we have assumed that log-normal mean trends represent the most likely. Measurement errors for the survey data and indices of relative abundance used to

Figure 14. Annual mean simulated stock and landings for the high-salinity (>14 ppt) model at 10–100% of baseline F. Stock results were smoothed by polynomial spline interpolation; landings results were not smoothed.

parameterize the model have been shown to be small relative to temporal and spatial variations in the oyster population (Jordan et al. 2002, Jordan 1995), and will not be considered further here.

Parameter values are accurate only to the extent that the assumptions made in estimating them are valid. The use of box counts to estimate annual natural mortality has been a subject of investigation (Christmas et al. 1997, Powell et al. 2001, Powell et al. 2002) and was discussed in the context of the current study by Jordan et al. (2002). We conclude that because annual natural mortality estimated from box counts was strongly correlated with trends in the live oyster population (market oyster biomass: $r = -0.60, P = 0.01$) and landings ($r = -0.58, P = 0.02$), the method is sufficiently accurate.

The estimates of fishing mortality are based on an assumption tested only by the comparison of hindcast results to landings data

Figure 16. Percentages of iterations of the low-salinity (<12 ppt) model that indicated stock restoration (market stock $\geq 1.1 \times 10^6$ bushels) at 10–100% of baseline F.

(Fig. 2) and by the generally reasonable nature of simulations. Fishing mortality rates reported from prior stock assessments bracket our mean estimate ($F = 0.71$) for 1986–2001. Cabraal (1978) reported $F = 0.27$ from analysis of catch and effort data for 1975–1976, with a market oyster stock of 10.4×10^6 bushels and landings of 2.5×10^6 bushels. Rothschild et al. (1994) calculated $F = 1.3$ for the 1991 Maryland oyster harvest; we used Smith and Jordan's (1993) finite exploitation rate of 0.53 ($F = 0.64$) for the same year to scale F from relative to absolute values. Jordan et al. (2002) showed that the Rothschild et al. (1994) estimate was probably too high because of errors in specifying natural mortality and growth. Because this model is sensitive to F , a focus of this study, the estimates need better verification. The methods used to harvest oysters in Maryland are inherently inefficient (except for diving, a minor component of the fishery), thus very high values of F probably would require more fishing effort than would be returned by the value of the catch. High rates of effort might occur locally, or for brief episodes (viz. $F = 1.29$ for 1989), but should not be sustained.

The two mortality terms in the model, M and F , are strictly additive and do not interact. A model by Klinck et al. (2001) of the New Jersey oyster fishery in Delaware Bay predicted higher yields by adjusting fishing seasons to compensate for high rates of disease-related natural mortality. In effect, natural mortality could be decreased by concentrating the fishery in late spring, earlier in the year than most of the disease-related mortality. Moreover, much of the recruitment to market stocks in mid-Atlantic estuaries probably occurs in spring (April–May), when oyster growth rates tend to be high. For these reasons, stock size should peak in late spring. Klinck et al. (2001) used a daily time step and separate functional forms for M and F in their model. Unlike the New Jersey fishery, where a late spring–early summer harvest is traditional, the Maryland fishery has operated only in the fall and winter (October through March, with minor exceptions) for many decades. Although it is likely that higher yields could be achieved in Maryland at a given F with seasonal management, tactical fisheries management has not been the objective of this study. We have focused on long-term population restoration, for which an annual time step and additive mortality terms appear to suffice. Total annual mortality rate ($Z = M + F$) would not be affected by the compensatory mortality demonstrated by Klinck et al. (2001). From a long-term population or restoration perspective, it matters not how an oyster dies, only that it does.

We did not measure or validate directly the recruitment term (R) in the model; it was derived from year-to-year differences in the market stock, plus total mortality. Net recruitment [$dS/dt = r = R - (M + F)$], the rate of change in stock size, was consistent with observed long-term trends in relative stock biomass and reported landings. Gross recruitment rates were higher at higher salinity (Table 1), as expected because of higher spat settlement densities at higher salinity (Jordan 1995).

The estimates of carrying capacity (K), although based on the best available data, are uncertain and not directly verifiable. Fortunately, model results and conclusions are not especially sensitive to K , but low-mortality simulations for which the stock approaches K should be interpreted more cautiously than others. Our only verification of this parameter is that K for the bay-wide model ($\sim 17 \times 10^6$ bushels) is reasonable with respect to historical landings, which peaked at 10 to 15×10^6 bushels in the 1880s. Although K is a constant in this model, it certainly varies in the real world. Long-term declines in the quantity and quality of oyster

habitat (factors of K) in Maryland have been reported (Rothschild et al. 1994, Smith et al. 2001).

Besides uncertainties in estimating model parameters, the governing logistic equation may not accurately represent oyster population dynamics. A particular concern is the stock-recruitment (S/R) relationship. In this model, the rates of gross recruitment (R) and net recruitment (r) are not correlated with stock size, but the average absolute number of recruits increases linearly as the stock increases. The logistic formulation we use artificially limits stock size as a function of K without directly affecting the randomly input recruitment and mortality rates, in which density-dependence would be expressed in nature. Observations in Maryland have shown that oysters can produce high densities of spat at very low population levels; for example, two of the highest spat density indices on record were in 1991 and 1997, when adult population densities were very low (Maryland DNR 2001). This fact suggests that the S/R curve could be steep at low stock sizes, and if so, the model is conservative with respect to recruitment in these cases. Conversely, two major sources of natural mortality, diseases and predation, could be more intense at higher oyster densities, suggesting that the model could overestimate recruitment at moderate stock size; that is, the S/R curve could be flatter at moderate stock size than predicted by the logistic model (at large stock sizes, approaching K , errors in R would make little difference). Estimated stock size varied from 0.18×10^6 to 3.21×10^6 bushels (1–19% of K) during the time series of data used to parameterize the model, so we have observed only a minor portion of the S/R relationship, if indeed there is one. During this period, gross annual recruitment (R) ranged from 40% to 80% of the stock, without any obvious pattern. We quote Cushing (1968, p. 124): "... there is very often no relation between parent stock and subsequent recruitment at those levels of stock which support fisheries."

Implications and Recommendations for Management

The model indicates that long-term average recruitment rates should be ample to replace or rebuild Maryland oyster stocks if mortality rates could be reduced sufficiently. Natural mortality cannot be managed to a significant degree so long as parasitic diseases kill large proportions of oysters. If the population is developing disease resistance through natural selection, the process has been too slow to observe. Selective breeding and introduction of disease-tolerant oyster strains for restoration purposes have not been implemented at a scale that could make more than a local difference. Attempts to improve management by restricting movements of infected seed oysters have had no measurable effects at the population scale.

Fishing mortality, in principle, is entirely controllable. The Maryland oyster fishery is regulated by gear restrictions, seasonal and area closures, a minimum size limit, daily catch limits, license surcharges, and limited entry. These restrictions, most of which pre-date the major impacts of Dermo and MSX diseases, apparently have not been sufficient to maintain sustainable rates of fishing mortality while natural mortality rates are high. Annual indices of relative and absolute stock size (Jordan et al. 2002) are available that could be used to limit fishing mortality by setting a total allowable catch (TAC), based on a conservative F , for each year. The fishery could then be closed whenever in the season the TAC was attained, or effort could be otherwise limited so as not to exceed the TAC. The Maryland bay-wide model indicates that reducing average F by 40% ($F = 0.43$) to 50% ($F = 0.35$) would

virtually assure stock restoration and an enhanced fishery within a decade.

As an example, the estimated initial stock for the 2000–2001 oyster season was 702,000 bushels (Table 1), which produced landings of 348,000 bushels ($F = 0.70$, near the long-term mean). At $0.4F$ ($F = 0.43$), landings would have been about 245,000 bushels, and at $0.5F$ ($F = 0.35$), about 207,000 bushels. These losses to the fishery would be economically significant (\$2–4 million in dockside value) in the short-term, but more than compensated in the long-term. With $F = 0.43$, the model predicts average landings of 656,000 bushels for 2001–2020 and average landings $>1 \times 10^6$ bushels in the second decade of the simulation.

Model scenarios indicated little likelihood of rebuilding the stock or increasing landings by managing fishing mortality in the high-salinity zone. Maryland uses higher salinity areas, where spat settlement is relatively high, for seed oyster production. Large plots are shelled each summer to stimulate spat settlement. The following spring, the spat and shell are transferred to lower salinity areas where disease-related mortality is less. In effect, this strategy enhances recruitment in low-salinity areas, where natural recruitment is undependable. The bay-wide and low-salinity versions of the model implicitly include this source of recruitment, because some of the low-salinity monitoring sites were supplied with transferred seed oysters in most of the baseline years of this study. Because it is unlikely that a significant harvestable stock can be restored in the high-salinity zone, seed oyster production for supplementation of low-salinity areas is probably the best management strategy for this zone. There are benefits to stimulating recruitment through hatchery spat production, but cost and logistical constraints should be expected to limit this contribution to roughly the 10% increase in recruitment we have simulated (Figs. 6, 7, and 15).

Model predictions are most promising for the medium-salinity zone. This large area benefits from moderate to high spat settlement in some years and also from episodes of low salinity that can diminish disease-related mortality for one or more years. The model indicates that a sanctuary strategy alone could have modest success in this zone, in contrast to the low- and high-salinity zones. Management for this zone could use sanctuaries, closed to harvest and stocked with seed oysters, in combination with explicit reductions in fishing mortality, to rebuild productive stocks.

A productive oyster fishery was sustained in Maryland until repeated disease epizootics drastically increased natural mortality

rates beginning in the 1980s. Fishing mortality rates, meanwhile, remained constant or increased. Recruitment, whether stable or declining, could no longer keep pace with total mortality rates and the stock declined. This dynamic has continued into the 2000s. Strategies intended to increase recruitment (habitat improvement, natural and hatchery seed oyster production) have been used extensively, but they are expensive, have not stemmed the decline, and offer only marginal hope for the future.

Preliminary landings for the 2002–2003 Maryland oyster season are 51,145 bushels, about 2% of 1975 landings and 3% of 1986 landings. At a dockside value of no more than \$1.5 million, the fishery is close to economic extinction. We recommend that it is past time to reduce and control fishing mortality specifically to restore the oyster stock. With F set at 0.43 ± 0.25 (standard deviation) in 1986 and maintained at that level, mean simulated 2002–2003 landings would have been 1.96×10^6 bushels, 38 times the reported quantity. Ecological contributions (Jordan 1987, Newell 1988, CBP 2002) would have multiplied by roughly the same factor. Taking this action in 1986 would have caused a loss of nearly \$9 million in dockside value to the fishery for that year, but the loss would have been repaid many times in sustainable harvests and ecological services.

ACKNOWLEDGMENTS

We greatly appreciate assistance, advice, and support from staff of the Maryland Fisheries Service and Sarbanes Cooperative Oxford Laboratory, especially Mark Homer, Kelly Greenhawk, Gary Smith, Mitchell Tarnowski, and Jim Uphoff. This model was made possible by the long-term data collection efforts of many people from the Maryland Department of Natural Resources. William Fisher provided a thoughtful preliminary review of the manuscript. Financial support was provided by the Maryland Department of Natural Resources, the National Oceanic and Atmospheric Administration Chesapeake Bay Office, and the U.S. Environmental Protection Agency Chesapeake Bay Program. The information in this document has been funded in part by the U.S. Environmental Protection Agency. It has been subjected to review by the National Health and Environmental Effects Research Laboratory and approved for publication. Approval does not signify that the contents reflect the views of the agency, nor does mention of trade names or commercial products constitute endorsement or recommendation for use. This is contribution number 1185 of the Gulf Ecology Division.

AGE STRUCTURE AND GROWTH IN AN UNUSUAL POPULATION OF PURPLE CLAMS, *AMIAANTIS PURPURATUS* (LAMARCK, 1818) (BIVALVIA; VENERIDAE), FROM ARGENTINE PATAGONIA

ENRIQUE M. MORSÁN¹ AND J. M. (LOBO) ORENSANZ²

¹Instituto de Biología Marina y Pesquera "Almirante Storni," Universidad Nacional del Comahue and Dirección de Pesca de Río Negro, P.O.Box 104, (8520) San Antonio Oeste, Argentina; ²Centro Nacional Patagónico (CONICET), (9120) Puerto Madryn, Argentina

ABSTRACT The purple clam, *Amiantis purpuratus*, is distributed in the southwest Atlantic between Vitória (Brazil, 20° S) and San Matías Gulf (Argentina, 41° S). We studied the age structure and growth in its southernmost population, which sustains small artisanal and sport fisheries. Examination of individuals collected in 1995 revealed well-marked external growth bands on the shells and a puzzling pattern: most had 15 or 16 bands. Were these annual, the implication would be virtually no successful recruitment during the 14-year period 1981–1994. We recovered and processed samples collected in the same area in 1980–1983 and 1987–1990 and conducted a comprehensive survey of the population in 1995. Examination of thin shell sections showed an almost exact correspondence between internal and external bands. The time series of size-at-age data indicated a bi-univocal correspondence between years lapsed and number of bands accumulated. This confirmed that external bands are annual and that only two significant year-classes (1979 and 1980) settled in the study area over a period of at least 15 years (1979–1994). Growth was studied at one location using size-frequency distributions and size-at-age data. Comparisons were made using likelihood methods to test differences among year-classes (1979, 1980, older) and between two sites. Differences between the 1979 and 1980 year-classes were insignificant at both sites. Growth rate estimated for a pool of pre-1979 year-classes was high when compared with the 1979–1980 year-classes. Density dependence is advanced as a hypothesis to explain the comparatively slow growth of the 1979–1980 year-classes. Longevity is above 25 years. Implications of the findings for conservation and management are discussed.

KEY WORDS: *Amiantis*, purple clam, growth, age, recruitment, southwest Atlantic

INTRODUCTION

The purple clam, *Amiantis purpuratus* (Lamarck, 1818), inhabits intertidal and shallow subtidal sandy bottoms along the Atlantic coast of South America, from 20°S to 41°S (Scarabino, 1977; Rios, 1994) (Fig. 1A). The southernmost population within this broad latitudinal range, confined to the northwest of San Matías Gulf (Fig. 1B), appears to be relatively isolated. This is, also, the only stock of the species subject to exploitation. What started as a recreational intertidal fishery in the area of Playa Villarino (Fig. 1C) has evolved since 1996 into a small-scale commercial diving fishery. Annual catch peaked at 382 t in 1996, and since then has fluctuated around 100 t. A preliminary survey conducted in 1995 revealed that (i) there were no juveniles, (ii) clam shells had very conspicuous external bands, and (iii) most shells had 15 or 16 bands. If those bands were laid annually, these preliminary observations would imply that the purple clam is a long-lived species, that the incipient fishery was based on two year-classes, and that pulses of recruitment are very sporadic. These prospects raised concerns with regard to the conservation of this fringe population and the sustainability of the fishery that it supports. Because there were no published antecedents on purple clam biology and ecology, we initiated a study to investigate the dynamics of this population. The first step was to develop reliable aging techniques. The simplest method traditionally used to age bivalves is based on the interpretation of external growth rings on the surface of the shells, often formed during the winter in cold-temperate seas (Richardson and Walker, 1991). In many species, however, such rings are absent or are difficult to interpret (Richardson et al. 1993). An alternative method is the study of the optical pattern of internal bands in shell cross-sections, using either acetate peels or thin sections (Cerrato 2000). Internal growth bands are more clearly defined and easier to count in shell structures such as hinge plates and chondrophores (Palacios et al. 1994; Thompson et al. 1980).

The external growth rings of purple clam shells are very conspicuous, with an alternation of thick dark purple and thin pink bands. Here we report results on the nature of internal growth bands, on the matching between external rings and internal bands, and on their periodicity. Based on age data and on the analysis of size-frequency distributions, we estimated growth parameters, compared growth curves between cohorts and between sites in the study area, and advanced hypotheses on the causes of the variation observed. This is the first study of this type conducted for this potentially significant shellfish resource. Implications of our results for the dynamics of the population and the management of the fishery are discussed.

MATERIALS AND METHODS

Study Area

Playa Villarino (Fig. 1C) is a 9-km long dissipative sandy beach located in the proximity of San Antonio Bay (NW of San Matías Gulf). Average tidal amplitude is 7.62 m (maximum 9.2 m); in low tide the beach is 450–600 m wide. Sediment is predominantly fine sand, with patches of shell hash. Water temperature ranges, on average, from 6°C in August (winter) to 22.5°C in January (summer) (Kroeck and Morsán 1995). Water circulation in the NW of San Matías Gulf was described by Lanfredi and Pousa (1988) as a clockwise coastal eddy predominantly influenced by tidal currents, with limited interaction with the general circulation in the gulf. The population under study is distributed in the intertidal and subtidal zones, down to 10 m depth in low tide. The macrofauna is dominated by the purple clam (average biomass: 3235 g m⁻² in a survey conducted in 1995; Morsán, 2000), followed by two scavenging/carnivore gastropods: *Buccinopsis gobulosum* (NASSARIIDAE) and *Olivancillaria urceus* (OLIVIDAE).

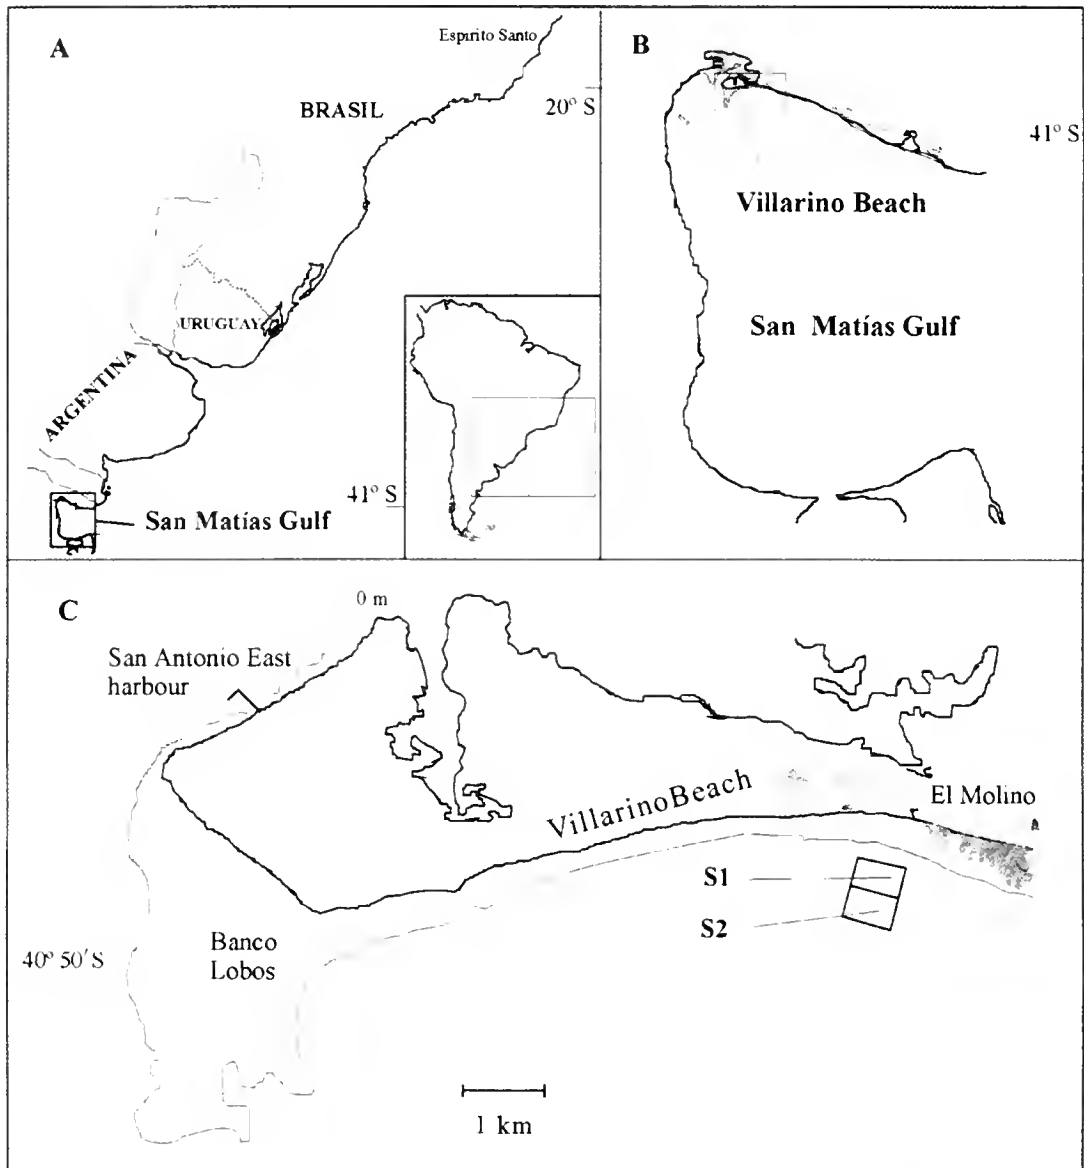

Figure 1. (A) Geographic distribution range of the purple clam, *Amiantis purpuratus*. (B) San Matías Gulf and Villarino Beach. (C) Location of sampling sites at El Molino (S_1 and S_2).

Study Site

Studies on age and growth were conducted at El Molino (Fig. 1C), a site located near the eastern end of the beach where periodic samples were obtained within a rectangular plot (500 m \times 1000 m) perpendicular to the shoreline. Depth varies from 3 m to 9 m; strata were defined as the shallow (average depth 3.2 m) and deep (average depth 7.7 m) halves of the plot, respectively designated as sites S_1 and S_2 . Maximum density during the 1995 survey was 368 clams m^{-2} in S_1 and 216 clams m^{-2} in S_2 .

Sampling Protocol

Samples were obtained by divers between 1980 and 1995 (Table 1). Sampling units consisted of 0.25- m^2 quadrats dug to a depth of 20 cm. On a few occasions, samples were qualitative although obtained in a nonselective way. Between 1980 and 1983

clams were dug manually; an airlift was used starting in 1987. Total height (maximum distance from umbo to ventral margin) was recorded for all clams. The samples were obtained during three time intervals, under different arrangements (Table 1):

- (1) 1980–1983: These samples, obtained before the beginning of our project, were believed to be lost. We reconstructed their fate, tracked their location, and finally recovered them through a sequence of serendipitous circumstances. They proved extremely valuable. The data include date, position, number of individuals, and individual sizes for 15 samples, and two sets of valves collected in 1982. The shells of individuals collected in October 8, 1982, that had presumably settled before 1979 (based on external bands, $n = 104$) were selected for aging.
- (2) 1987–1990: Periodic sampling. One sample was used for age determination ($n = 55$).

¹ External bands counted but not measured.

² External bands counted and measured.

³ External bands counted but not measured.

⁴ External bands counted and measured; internal bands counted.

(3) 1995: Quantitative survey of the entire population, conducted in March 1995. Individuals from two samples were used for age determination.

Analysis of SFDs

Size data were grouped at 1-mm intervals. Mean size, standard deviation, and proportion of each annual separable modal group were estimated for each sample unit. In some cases the groups could be identified visually. When modal groups overlapped, the decomposition was done by means of maximum likelihood methods, assuming that the components were normally distributed (MacDonald & Pitcher 1979).

Age Determination

Subsamples from five samples were used for aging (Table 1). Of these, two subsamples from the 1995 survey were used to study external and internal bands. External bands were counted and measured in a third subsample (sample collected on October 8, 1982), and only counted in two subsamples (samples collected on February 1, 1982, and February 1, 1990).

The external banding pattern of purple clam shells is very conspicuous, with an alternation of thick dark purple and thin pink bands. We counted the number of pink narrow bands; the beginning of the well-defined pink band was defined as the boundary between two consecutive bands. Bands were measured (distance from the umbo to the distal border of the band) along the same axis used to measure total height and to cut the shells for the observation of internal bands (see below).

To count internal bands, thin sections were obtained, cutting each valve with a low-speed diamond saw along the same axis used to count and measure external bands, running from the umbo to the ventral margin through the hinge plate. The surface left by the cut of one of the two valve halves was ground and polished using sandpaper of very fine grain (4000 grit) on a rotating platform at variable speed. The polished surface was glued with epoxy resin to a microscope slide. A 0.5-mm thick slice was obtained by means of a second cut along a plane parallel to the slide's surface. The exposed face of the thin section was ground and polished with sandpaper of medium grain (1000 grit) and very fine grain (4000 grit) until adequate thickness and texture were reached. Mounted thin sections were examined under a dissecting scope with trans-

mitted light to identify internal growth bands and to establish their correspondence with external bands.

Growth Modeling

Growth was modeled using (i) size-frequency distributions (SFDs) obtained between 1980 and 1995 and (ii) size-at-age back-calculated using external band measurements (H_t , where t indicates the boundary sequential number counting from the umbo) in samples collected in 1982 and 1995 (Table 1). Likelihood methods were used to fit the von Bertalanffy growth model.

$$H_t = H_\infty (1 - e^{-k(t-t_0)}) + \varepsilon.$$

where H_∞ is asymptotic shell height (expressed in mm), k is a constant (expressed in yr^{-1}), t is age (in years), t_0 is the age at size zero and ε is an error term distributed normally ($\varepsilon \sim N(0, \sigma)$). In doing so, we assumed that external bands are laid down annually (see Results for validation of this assumption). The likelihood ratio test was used to compare growth curves between cohorts and/or locations (Kimura 1980; Cerrato 1990). Null hypotheses are of the form

$$H_0 : H_{\infty,1} = H_{\infty,2}, \dots; k_1 = k_2, \dots; t_{0,1} = t_{0,2}$$

and combinations of them, where 1 and 2 denote the two statistical populations being compared. Under the null hypothesis, the test statistic $-2\log(\Lambda)$ converges asymptotically to a $\chi^2_{(g)}$ distribution with g degrees of freedom (equal to the number of fixed parameters).

RESULTS

Age Determination

Matching between external and internal growth bands (Fig. 2) was almost perfect. Internal growth lines are more evident in the hinge plate when the cut is perpendicular to the valve and runs across one of the cardinal teeth. Clams sampled during the late summer of 1982 ($n = 163$, Table 1) had two or three pink bands. Eight years later, in late summer 1990, individuals ($n = 58$) collected in the same location showed 10 or 11 bands. Finally, most individuals (97%) in two samples collected during late summer in 1995 ($n = 180$ and 160, Table 1) had 15 or 16 bands (Fig. 3). This

Figure 2. Growth pattern in the shell. (A) External view of a shell showing the external growth bands; (B) cross-section through the hinge region of a 13+ year-old individual.

indicates that between 1982 and 1995 the population was dominated by two year-classes and confirms that internal and external bands are laid annually. A dark purple band was visible along the border of the valves in all specimens collected in late summer. Summer is the spawning season of the purple clam in Villarino. Although the length of the larval stage is unknown, settlement is assumed to occur in late summer. Purple clams would mark their first clear growth band during the following winter. If this interpretation is correct, then the two cohorts must have settled during late summer in 1979 and 1980. The number of bands in shells from

Figure 3. Correspondence between time elapsed between sampling dates and hands accumulated. Empty circles, 1979 cohort; solid circles, 1980 cohort. Percentages refer to number of individuals aged per sample.

old clams collected on 10/8/1982 (Table 1) varied from 9 to 18, indicating that they settled during the period 1965–1974. These cohorts had vanished from the population in 1995. The maximum number of bands recorded (i.e., maximum inferred longevity) was 42 years.

SFD Analysis

The progression of SFDs from 1980 to 1995 is shown in Figure 4 (seasonal pools, only six periods represented). Individuals smaller than 25 mm prevailed between 1980 and 1983, with the exception of a few larger than 40 mm. Between 1987 and 1990, most of the clams ranged between 25 and 35 mm. Finally, in 1995, most clams were larger than 35 mm. No juveniles were found after 1982. Two modal components were clearly distinguishable in the SFDs through 1987; afterward they overlap, making their recognition difficult. The presence of two consecutive cohorts in each of the subsamples used for aging (Table 2) is consistent with the two modal components observed in the SFDs, presumably corresponding to the year-classes settled in 1979 and 1980. The mean size of modal components estimated for all sampling units clearly shows the growth of these two cohorts between November 1980 and May 1995 (Fig. 5).

Growth

Growth rate was very similar between the 1979 and 1980 cohorts (Fig. 6). Although the complete parameter vectors were significantly different (H_04 , Table 2), pairs of analogous parameters do not show significant differences ($P > 0.05$, H_01 – H_03 , Table 3). Parameters H_x and k were analyzed together in a single test (H_05). The null hypothesis was rejected only for estimates based on growth-band data. Differences between the 1979 and 1980 cohorts were not significant within each stratum, although differences between strata were significant for both cohorts (H_05 , Table 3). Parameter k did not differ significantly between groups in any case. Difference between sites was driven by parameter H_x , which was higher in the deepest stratum where density was lower. Growth parameters estimated on the basis of size-at-age back-calculation for the multicohort group sampled in 1982 were higher than those of the 1979–1980 cohorts (Fig. 6). The null hypothesis of equal growth coefficients (k) could not be rejected, but all others were ($P < 0.01$).

DISCUSSION

When a preliminary survey of purple clams was conducted in Playa Villarino (San Matías Gulf, northern Argentine Patagonia) during the summer of 1995, some aspects of this population proved intriguing. First, there were no juveniles; second, most shells had 15 or 16 conspicuous external bands. If interpreted as annual, these preliminary observations would imply that the purple clam is a long-lived species, that the incipient fishery was based on two year-classes, and that pulses of recruitment are very sporadic. Collating information obtained during three intervals over a period of 15 years (Table 1) confirmed that, indeed, the population had been dominated all along by two year-classes, presumably settled during the summers of 1979 and 1980. Three pieces of information are remarkably consistent with each other, substantiating that hypothesis: (i) the number of external bands increased bi-univocally with time over the years (Fig. 3), (ii) there was an almost perfect correspondence between external and internal bands (Fig. 2), and (iii) the progression of SFDs through time show a modal structure that

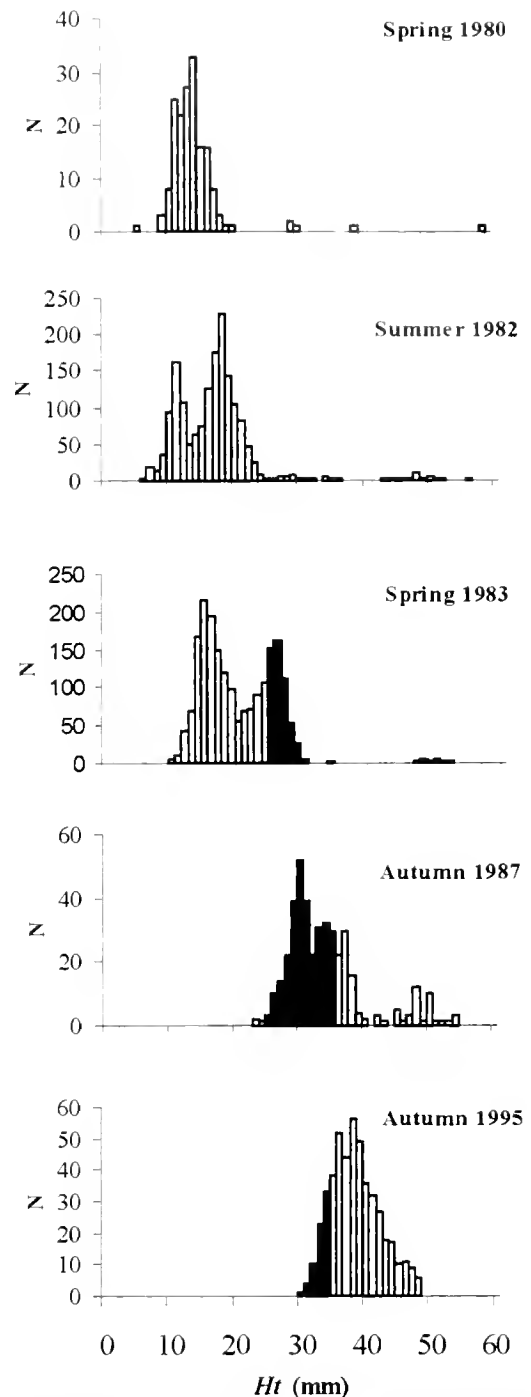

Figure 4. Size-frequency distributions (SFDs) during the period 1980–1995. Samples were pooled into several seasons. Solid bars indicate the range 25–35 mm for visual reference.

matches the age structure inferred from the analysis of growth rings (Fig. 4).

The recovery of data and samples collected in 1980–1983 (presumed lost) was most significant for the interpretation of the data. Shells collected at that early time in the life history of the two cohorts facilitated tracking the latter through time and validation of growth marks. External annual bands in this purple clam stock are among the clearest reported for bivalves, to the extent that we first thought of them as an endogenous sculpture pattern. This may be

TABLE 2.

Growth parameters estimated for different cohorts at El Molino, using size-at-age and size-frequency distribution (SFD) data.

Cohorts	Site	Size-at-age Data			SFD Data		
		k	H_{∞}	t_0	k	H_{∞}	t_0
1965–74		0.154	57.2347	-0.246	—	—	—
1979	El Molino	0.1329	43.545	-1.412	0.149	44.125	-0.424
1980		0.1333	42.025	-1.199	0.095	48.971	-0.863
1979	S ₁	0.1340	40.533	-1.402	0.1758	40.925	-0.375
	S ₂	0.1233	45.631	-1.820	0.1390	47.553	-0.030
1980	S ₁	0.1385	40.947	-1.038	0.1185	43.649	-0.679
	S ₂	0.1159	45.208	-1.820	0.1028	48.906	-0.399

due in part to the strong seasonal variation in temperature and in part to the fact that the porcelain-textured and color banding of the outer surface of the shells, which are rarely deteriorated, greatly facilitate observation.

The virtual absence of new settlers during the 15-year period 1981–1995 indicates that the population is sustained by very sporadic pulses of settlement/recruitment. This could be explained by two hypotheses. The first, and most obvious, is dependence of reproductive success on suitable combinations of environmental conditions (environmental windows) that occur only sporadically. This is to be expected: this being the southernmost population of the species,³ those windows may open up only occasionally. The dynamics of the purple clam may be representative of that of other species in the same region. Biogeographically, the northwestern corner of San Matías Gulf is an enclave where populations of several warm-temperate species live in apparent isolation, southward from their normal range of distribution. There is evidence of the recent local extinction of some of those, for example, the common drumfish (*Pogonias chromis*, Sciaenidae), whose otoliths are found in shell middens but which has not been recorded in the region during historical times. Sporadic pulses of recruitment may be indicative of the dynamics of extinction, perhaps the fate of this population unless there were a significant change in the environment (e.g., global warming) that reverses the trend.

A second plausible hypothesis that could explain sporadic settlement/recruitment is density dependence. Density and biomass observed during the 1995 survey (15 years after the settlement of 1979–1980 cohorts) were very high (Morsán, 2003), and rough back-calculations indicate that they must have been so over the preceding years. Compensatory density-dependent settlement in dense populations of suspension-feeding bivalves has been documented or hypothesized for other populations (Wilson 1991; Bachelet et al. 1992). If the density of residents were inhibiting the settlement/recruitment of new year-classes, the effects of density dependence should likely be observed in growth as well. Interestingly, individuals of the 1979–1980 year-classes reached comparatively small sizes-at-age. Asymptotic height estimated with different methods was in the range of 40–49 mm. By comparison, Carcelles (1944) reported much larger specimens (maximum height 72 mm) collected at the same location (Playa Villarino) during the period 1923–1933, close to maximum height reported for the species (73 mm, in subfossil deposits; Camacho 1966).

Size-at-age (Figs. 5 and 6) and estimated growth rate (overall sizes, Fig. 7) were much higher when estimated with data from a subsample of shells settled before 1979 (1965–1974), collected in October 1982. As compared with the 1979–1980 cohorts, asymptotic size was much higher in this multicohort group (57.2 mm) although differences in parameter k of the von Bertalanffy model were not significant (Table 3, Fig. 7). According to general theory (Sebens 1987) and empirical evidence (Guillou and Sauriau 1985; Harrington 1987), differences in k (which reflects catabolic activity) should be influenced by temperature, whereas variation in asymptotic size should reflect food availability. The latter should

³A few isolated individuals have been found further south, in San José Gulf (El Fracaso and El Riacho Beaches, JO, personal observation), but they do not seem to belong to a self-sustaining population. These are considered here as extralimital records.

be affected by density, at least under high-density conditions such as observed during the survey when density reached 620 clam m⁻² (corresponding to a biomass of 10 kg m⁻²; Morsán, 2003). Density-dependent growth in clams, long hypothesized and demonstrated experimentally under field conditions (e.g. Peterson 1982; Peterson and Black 1987), is proposed here as a hypothesis to explain the comparatively low growth rate of the 1979–1980 year-classes. It is interesting that although there was a big difference in asymptotic size, there was virtually no difference in parameter *k*, even when the pattern could have been concealed by structural correlation between the two parameters. This hypothesis will be explored in a forthcoming study.

Figure 7. Estimated growth rate as a function of size. Cohorts compared, age data.

The oldest specimens belonging to pre-1979 year-classes collected in 1982 were 17 years old. The 1979–1980 year-classes were 16–17 years old when the 1995 survey was conducted. Recent informal observations by one of us (EM, 2003) indicate that those two strong year-classes still dominate the population about 25 years after they settled. This, thus, is a low bound to longevity. The latter was higher than we had expected for a warm-temperate, shallow-water venerid clam. Other species in the same subfamily (Pitarinae), however, are also reportedly longevous: 76 years in *Callista brevisiphonata* (Zolotarev 1980) and 40 years in *Callista chione* (Powell and Cummins 1985).

The exploitation of a population that (i) is isolated at the boundary of the species' geographic range of distribution and (ii) depends on very sporadic pulses of recruitment brings up concerns regarding management and conservation. The population may persist because significant longevity bridges long periods with no recruitment ("storage effect"; Warner and Chesson 1985), but reduced survival due to harvesting could shorten the effective length of those bridges. At the same time, however, there is the possibility that settlement of new cohorts was inhibited in a high-density scenario driven by two exceptional year-classes. If that were the case, thinning of the aging population through harvesting could alleviate overcompensatory density dependence, "creating room" for new settlers. These hypotheses could be explored through ex-

SEASONAL CHANGES IN BIOCHEMICAL COMPOSITION OF THE CLAM, *EURHOMALEA EXALBIDA* (BIVALVIA: VENERIDAE), FROM THE BEAGLE CHANNEL, ARGENTINA

BETINA J. LOMOVASKY,^{1,2,*} GABRIELA MALANGA,¹ AND JORGE CALVO¹

¹Centro Austral de Investigaciones Científicas (CADIC–CONICET), Ushuaia, Tierra del Fuego, Argentina; ²Ecología, Departamento Biología, FCEyN, Universidad Nacional de Mar del Plata, Mar del Plata, Argentina

ABSTRACT Seasonal changes in biochemical composition (protein, glycogen, and lipid content) of different organs (FV, foot-visceral mass; M, adductor muscles; and GMS, gills-mantle-siphons) of the clam *Eurhomalea exalbida* from Ushuaia Bay (54°50'S, Beagle Channel, Tierra del Fuego) were examined to describe changes in relation to reproduction and growth. A maximum level of protein content was observed during winter in all tissues with other increase during the spawning event (November) in FV and in November and January in GMS. In the adductor muscle, the protein content shows low variability during the year, except in June. These results suggest that all these tissues are involved in the storage of proteins, which are thought to play a role in the gamete maturation. The percentage of glycogen content for FV, M, and GMS showed low values (0.03% to 4.7% AFDW) along the year, which suggests that this component did not have an important function as energetic reserve. Low values of lipid content for FV were found in November with increased levels in summer season. Thus, variations in lipid content can principally be related to gamete emission in November and gamete maturation in summer season. The high levels of lipid content in FV over the rest of the year, except in June, were correlated with the presence of mature gonads throughout the major part of the year. Therefore, our results suggest that in *E. exalbida*, (a) proteins are the most important component stored, and (b) the relative content of protein, lipid, and glycogen of the adult specimens vary seasonally in accordance with the reproductive cycle and the season of maximum shell growth; when the organism reaches reproductive maturity (summer), shell growth slows down because of reproductive investment.

KEY WORDS: Beagle Channel, biochemical composition, bivalve, clams, *Eurhomalea exalbida*

INTRODUCTION

Seasonal changes in biochemical composition (protein, glycogen, and lipid content) may be of great importance in relation to energy metabolism necessary to growth and reproduction (Jayabal & Kalyani 1986, Lodeiros et al. 2001, Navarro et al. 1989). In the tropical scallop *Lyropecten (Nodipecten) nodosus*, it was observed that when the organism reaches reproductive maturity, growth slows down as a result of the reproductive investment, and the biochemical composition may change according to the reproductive requirements (Lodeiros et al. 2001).

The relationship of the energy transfer between different tissues, their capacity of reserve amounts under food availability, and their positive relationship with the high temperature and gonadal maturation have been shown in different species of bivalve mollusks such as scallops (MacDonald & Thompson 1986, Robinson et al. 1981, Sundet & Vahl 1981, Villalaz 1994), mussels (Zandee et al. 1980), and clams (Robert et al. 1993, Urrutia et al. 2001). The scallops *Argopecten ventricosus* (Villalaz 1994), *Chlamys islandica* (Sundet & Vahl 1981), and *Placopecten magellanicus* (Robinson et al. 1981) stored glycogen and lipids in their adductor muscles and digestive gland, respectively, and used them up in gonadal maturation. The mussel *Mytilus edulis* (Zandee et al. 1980) stored glycogen in mantle and digestive gland during the period of food availability to be used in the gametogenic period. Alternatively, some bivalves (i.e., *Abra alba*, *Meretrix meretrix*) can obtain energy directly from food (Ansell 1974a, Jayabal & Kalyani 1986, Lucas 1996).

Biochemical component (lipids, proteins, or carbohydrates) fluctuations have been observed in bivalves and related to the reproductive cycle showing which components were the most important source of energy (Martínez 1991). Bivalves generally store

carbohydrates in large amounts during their growing season and use them over the rest of the year (Beukema 1997); although proteins may be an energy reserve in some bivalve species (Beninger & Lucas 1984, Brockington 2001, Galap et al. 1997). Lipid variation has principally been related to gamete development (Martínez 1991) with the highest levels of lipids during the period when gonads are ripe.

Eurhomalea exalbida (Dillwyn 1817) is a subtidal species with a wide geographic distribution all along the southern tip of South America, from the Chiloe Island (42°S) on the Pacific side (Dell 1964, Osorio et al. 1979, Soot-Ryen 1959) to the Beagle Channel (54°50'S), up to the Buenos Aires province (36°S) on the Atlantic side (Carcelles 1944, Carcelles 1950). *E. exalbida* is commercially exploited throughout the Pacific Coast of South America (Osorio et al. 1979). No records of commercial exploitation exist from the Atlantic side. The Beagle Channel population represents the extreme south of the species' distribution, withstanding large temperature variations (4–11°C), with marked seasonal variation in the biomass of phytoplankton (Hernando, pers. comm.). In the Ushuaia Bay (54°50'S, Beagle Channel), this clam shows a seasonal shell growth pattern (Lomovasky et al. 2002), with adult specimens growing in spring with shell growth slowing down in summer and juveniles growing in both seasons. The parameters of the von Bertalanffy growth function were estimated to be $height_{\infty} = 74$ mm, $k = 0.18$ y⁻¹, $t_0 = 0.15$ y, with a maximum age of 70 y reached (Lomovasky et al. 2002). This species was characterized by an important spawning event in November, followed by a quick recovering in summer with the presence of ripe gonads in the rest of the year (Morriconi et al. 2002). The monthly variations of the energetic content of different organ groups show a positive relationship between higher energy content and the presence of ripe gametes (Lomovasky et al. 2001).

Seasonal variations in growth and reproduction have been correlated with changes in the energy content of different organs (Jobling 1994, Lucas 1996), thereby reflecting the spatial and tem-

*Corresponding author. E-mail: lomovask@mdp.edu.ar

poral energy distribution within the organism. This distribution closely reflects the seasonality of the cost of reproduction and growth and the capacity to accumulate reserves within the organism (Martínez & Mettifogo 1998, Navarro & Torrijos 1995, Robinson et al. 1981, Zandee et al. 1980). Thus, the aim of the current work was to describe the biochemical seasonal changes in different tissues of the clam *E. exalbidus* from Ushuaia Bay and the relationship between the observed variations with the gametogenic activity and the maximum shell growth season.

MATERIALS AND METHODS

Samples of *E. exalbidus* were collected in Ushuaia Bay (54° 50' S, Beagle Channel; Lomovasky et al. 2002) in a subtidal flat at a depth between 2 and 4 m at low tide. Seasonal sampling was conducted by scuba diving between June 1999 and March 2000. Twenty to 30 clams, of shell length ≥ 38 mm (size at first maturity; Morriconi et al. 2002), were sampled each time ($n = 120$) and kept in aquarium for 24 h. Shell length (anterior-posterior axis, SL), measured to the nearest 0.01 mm and total weight (TW, ± 0.1 g) were recorded for each individual. Monthly mean surface temperature was recorded. The minimum mean seawater temperature (4.6°C) was recorded in August and the maximum (8.5°C) was recorded in February (Fig. 1).

After removing the valves, the sex of each individual was determined using gonadal smears. The soft parts were separated into three groups: foot-visceral mass (gonad, digestive gland, and gastrointestinal tract; FV), adductor muscles (M), and gills-mantle-siphons (GMS). These divisions were made based on the presence or absence of gonads in the tissues and on their potential capacity to fulfill a storage function (Lomovasky et al. 2001). The soft parts were dried at 80°C to constant weight and stored at -20°C until processing for biochemical analysis. Ash content was determined by igniting a subsample of tissue in a muffle furnace at 450°C for 24 h.

Condition Index

The relationships between shell length and FV dry mass, M dry mass, and GMS dry mass are represented (Lomovasky et al. 2002) by:

Figure 1. Monthly means of seawater temperature in Ushuaia Bay with maximum and minimum values between June 1999 and May 2000.

$$\log(\text{mass}) = a + b \times [\log(\text{SL})] \quad (1)$$

Seasonal condition values were analyzed using the condition index:

$$\text{CI} = \text{mass}/\text{shell length}^b \quad (2)$$

where b is the slope in (1), and were normalized using the relative condition index:

$$\text{RCI} = (\text{CI} - \text{mean CI})/(\text{SD of CI}) \quad (3)$$

To evaluate the null hypothesis of no difference between seasons in relative condition index in each of the organ groups (FV, M, and GMS), we performed an analysis of variance (ANOVA). The assumptions of normality and homogeneity of variances were tested, and the appropriate transformations were applied when necessary. Unplanned comparisons (modified Tukey test) were made when significant differences were found (Sokal & Rohlf 1995, Zar 1984).

Biochemical Composition

The biochemical composition of dry tissue subsamples from the three organ groups of approximately 20–30 individuals per season was analyzed. Proteins were determined after hydrolysis with NaOH 0.5 N and using BSA 1 mg/mL as standard following the method of Lowry et al. (1951). Glycogen of tissues was extracted by boiling with 30% (p/v) KOH and was determined as total carbohydrates using the method of the Anthrone reagent (Carroll et al. 1956, Seifert et al. 1949). Glycogen was quantified after precipitation with 99% (v/v) ethanol and using glucose standard solution containing 20 $\mu\text{g}/\text{mL}$. The difference between protein and glycogen content was considered as lipid content. The results were expressed as milligram (mg) biochemical component per gram (g) of tissue ash-free dry weight (AFDW).

Linear regressions were used to determine the possible relationship between the biochemical content (mg protein, glycogen, and lipid AFDW) of the three organ groups (FV, M, and GMS) and the size of the clams (SL) for each sex. As biochemical content (protein, glycogen, and lipid) per gram were found not to be related to the size of the organisms analyzed in this study, we performed an ANOVA to evaluate the null hypothesis of no difference between seasons in the biochemical content in each of the organ groups. The assumptions of normality and homogeneity of variances were tested, and the appropriate transformations were applied when necessary. A nonparametric test was used (Kruskal-Wallis) when required. Unplanned comparisons (modified Tukey test to parametric analysis or multiples contrast test to nonparametric analysis) were made when significant differences were found (Sokal & Rohlf 1995, Zar 1984).

RESULTS

Condition Index

Significant exponential size-mass relationships between FV, M, and GMS shell-free dry mass (SFDW) as dependent variables and shell length (SL) as the independent variable were found in females and males (Table 1).

The analysis of the relative condition index (Fig. 2A) for FV over time showed the highest values in January 2000 in both sexes whereas the lowest values occurred in June, September, and November for females and in September, November, and March for males (modified Tukey test, $P < 0.05$).

TABLE 1.

Size-mass relationships in *Eurhomalea exalbida* from Ushuaia Bay, Beagle Channel, as described by linear regression $\log Y$ (SFDM) = $a + b \times \log X$.

Y	X	Females				Males			
		a	b	r ²	n	a	b	r ²	n
FV	SL	-5.832	3.3199	0.64	109	-5.615	3.2104	0.45	97
M	SL	-5.1593	2.6909	0.63	109	-5.1156	2.661	0.48	97
GMS	SL	-4.9685	2.7252	0.73	109	-4.9496	2.7223	0.61	97

SL, shell length; FV, foot-visceral mass; M, adductor muscles; GMS, gills-mantle-siphons; SFDM, shell-free dry mass. All significant relationships ($P < 0.05$).

No significant changes in the relative condition index over time were found for either M or GMS in either sex (one-way ANOVA, $P > 0.05$, Figs. 2B and 2C).

Biochemical Composition

No significant dependence ($P > 0.05$) was observed for the relationships between the protein, glycogen, and lipid content and the size of the clams (SL) for each sex. Biochemical content (protein, glycogen, and lipid) per gram were found not to be related to the size of the organisms analyzed in this study.

Foot-Visceral Mass

The mean protein content (Fig. 3A) was significantly different between sexes (two-way ANOVA, $F_{\alpha=0.05,1,110} = 31.22$; $P < 0.001$). Significant higher values in June and November 1999 with minimum values in September 1999 and January 2000 (two-way ANOVA, $F_{\alpha=0.05,4,110} = 72.79$, $P < 0.001$; modified Tukey test, $P < 0.05$) in both sexes were observed. No significant differences were found in the protein content of FV attributable to date-sex interaction ($F_{\alpha=0.05,4,110} = 2.37$, $P > 0.05$).

Glycogen content was comparatively lower than the other components and varied between 0.2% to 4.6% in both sexes (Fig. 3B). No significant differences were found in the glycogen content between sexes (one-way ANOVA, $F_{\alpha=0.05,1,118} = 0.11$, $P > 0.05$). There were significant differences in glycogen content over time (Kruskal-Wallis; $H = 48.77$, $P < 0.001$) with the lowest values in June and November and the maximum value in January (multiples contrast test, $P < 0.05$).

Significant higher values in the FV lipid content in September 1999 and January 2000 in both sexes (for females: Kruskal-Wallis, $H = 37.31$, $P < 0.001$; for males: Kruskal-Wallis, $H = 39.60$, $P < 0.001$) were observed (Fig. 3C).

Adductor Muscles

Proteins were the major biochemical component of the adductor muscle (Fig. 4A). The average protein content showed significant differences between sexes (one-way ANOVA, $F_{\alpha=0.05,1,118} = 5.29$, $P < 0.05$), with slightly higher values in June 1999 in both sexes (females: Kruskal-Wallis, $H = 10.39$, $P = 0.034$; males: one-way ANOVA, $F_{\alpha=0.05,4,54} = 33.80$, $P < 0.001$; modified Tukey test, $P < 0.05$).

The mean glycogen content of M over time for females ($n = 61$) and males ($n = 59$) were significantly different (one-way ANOVA, $F_{\alpha=0.05,1,118} = 4.26$, $P < 0.05$). The differences among

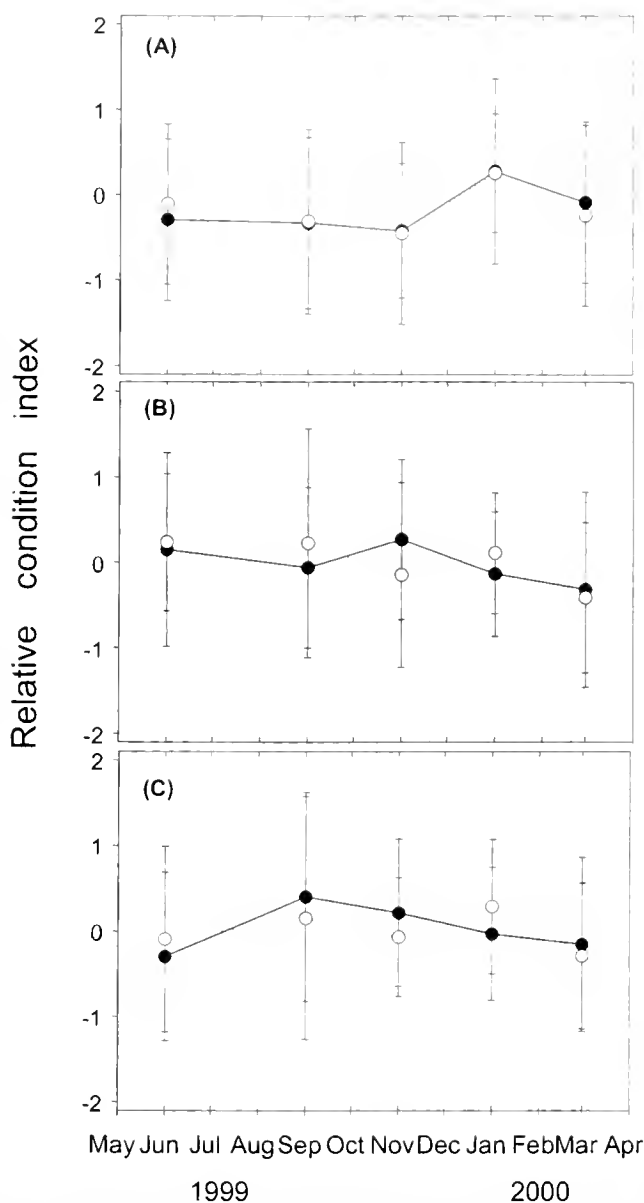

Figure 2. Relative condition index over time in *E. exalbida* from Ushuaia Bay: (A) foot-visceral mass, (B) adductor muscle, (C) gills-mantle-siphons. (●) females, (○) males.

the months were highly significant in both females (one-way ANOVA, $F_{\alpha=0.05,4,56} = 11.67$, $P < 0.001$) and males (Kruskal-Wallis, $H = 32.32$, $P < 0.001$). It was shown in the unplanned comparisons (modified Tukey test) that the glycogen content for females was significantly lower in June and September 1999 ($P < 0.05$) and higher in January and March 2000. Higher significant values in glycogen content among males occurred in November 1999 and January 2000 ($P < 0.05$) than in the rest of the year (Fig. 4B).

Significant differences in the lipid content (Fig. 4C) were found between sexes (Kruskal-Wallis, $H = 5.35$, $P < 0.05$), and over time for females (Kruskal-Wallis, $H = 11.27$, $P < 0.05$) and males (Kruskal-Wallis, $H = 33.49$, $P < 0.001$). Lipid content varied significantly among males during June 1999 and was significantly less ($P < 0.05$) than in the rest of the year. For females, the

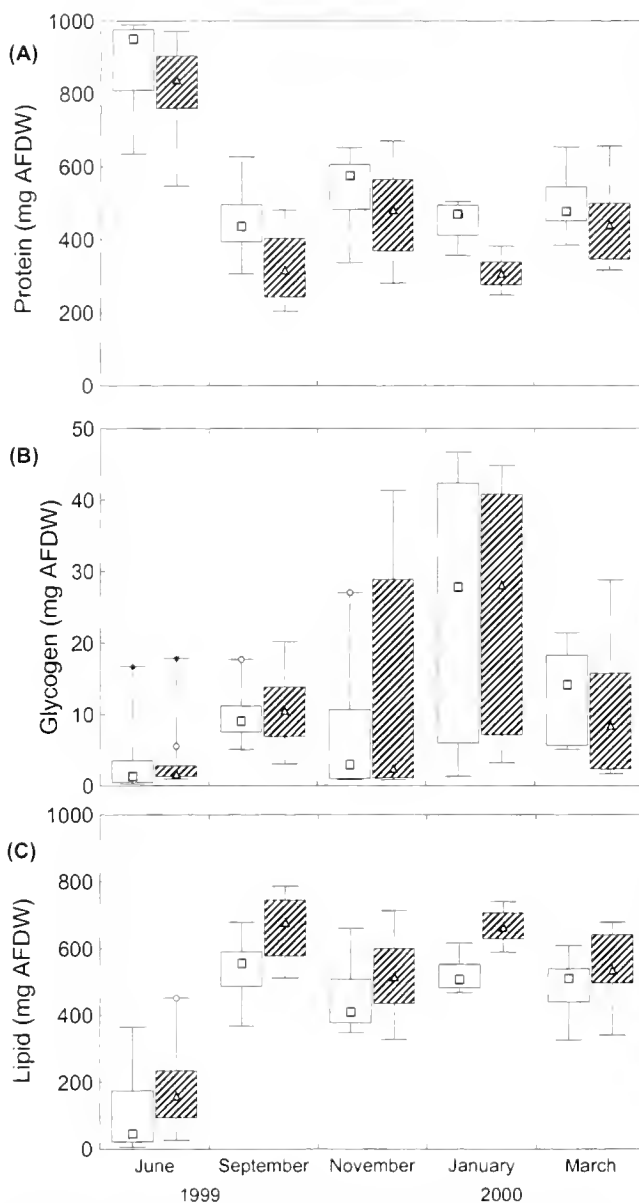

Figure 3. Seasonal variation in the biochemical components for foot-ventral mass (FV) in *E. exalbida* from Ushuaia Bay: (A) protein, (B) glycogen, and (C) lipid. Here and thereafter box plots are constructed with limits of boxes being the 75th and 25th percentile, lines represent maximum and minimum values, points inside boxes are medians, circles are outliers. White boxes: females; hatched boxes: males.

difference found was between the lesser value in June 1999 and the higher value in November 1999 ($P < 0.05$).

Gills-Mantle-Siphons

Protein content (Fig. 5A) was significantly the highest of the year in June and November 1999 and January 2000 in females (Kruskal-Wallis, $H = 42.59$, $P < 0.001$) and males (one-way ANOVA, $F_{\alpha=0.05,4,54} = 9.37$, $P < 0.001$). The average protein content was significantly different between sexes (one-way ANOVA, $F_{\alpha=0.05,1,118} = 12.53$, $P < 0.001$).

No differences (one-way ANOVA, $F_{\alpha=0.05,1,118} = 0.11$, $P > 0.05$) were observed between the mean values in glycogen

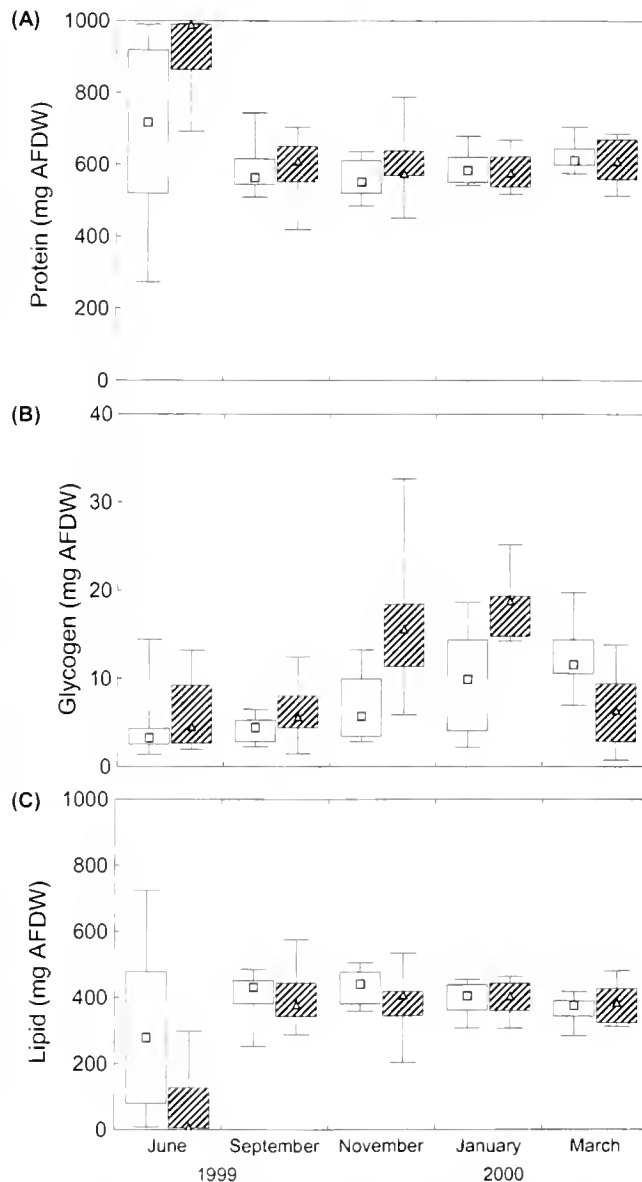

Figure 4. Seasonal variation in the biochemical components for adductor muscle (M) in *E. exalbida* from Ushuaia Bay: (A) protein, (B) glycogen, and (C) lipid. White boxes: females; hatched boxes: males.

content of females and males (Fig. 5B). There were significant differences in glycogen content over time (Kruskal-Wallis, $H = 44.73$, $P < 0.001$) with the lowest values in June 1999 and the maximum value in January 2000 (multiples contrast test; $P < 0.05$).

Significant differences in lipid content between sexes (Kruskal-Wallis, $H = 11.13$, $P < 0.001$) and over time in females (Kruskal-Wallis, $H = 42.55$, $P < 0.001$) and males (Kruskal-Wallis, $H = 26.21$, $P < 0.001$) were observed (Fig. 5C). Lipids were significantly highest in September 1999 and March 2000 in both sexes (multiples contrast test, $P < 0.05$).

DISCUSSION

The relative content of protein, lipid, and glycogen of the three organ groups for the adult specimens of *E. exalbida* from the

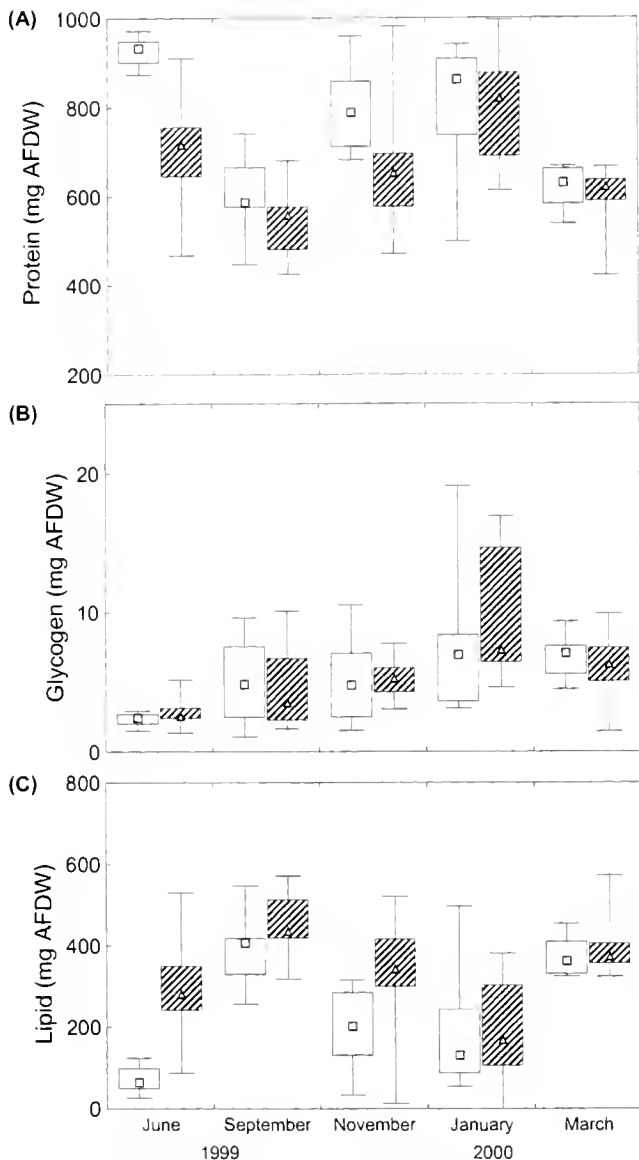

Figure 5. Seasonal variation in the biochemical components for gill-mantle-siphons (GMS) in *E. exalbida* from Ushuaia Bay: (A) protein, (B) glycogen, and (C) lipid. White boxes: females; hatched boxes: males.

Beagle Channel vary seasonally. These changes are principally related to the reproductive cycle and the season of maximum shell growth. Similar characteristics have been observed in other bivalves such as *Anomalocardia squamosa* (Morton 1978), *Donax trunculus* (Ramón et al. 1995), *Euvola (Pecten) ziczac* (Lodeiros & Himmelman 2000), *Lyropecten (Nodipecten) nodosus* (Lodeiros et al. 2001), *Macoma balthica* (Ankar 1980), *Mercenaria mercenaria* (Peterson & Fegley 1986), *Placopecten magellanicus* (MacDonald & Thompson 1986) and *Venus verrucosa* (Arneri et al. 1998).

The seasonal variations of the relative condition index for FV of *E. exalbida* were correlated with the gametogenic cycle (Morriconi et al. 2002) and the monthly relative condition index (Lomovasky et al. 2001) previously observed for this species. The lower RCI value was found in November in coincidence with a higher percentage of partially spawned stage (58.33% for males

and low mean number of mature oocytes for female; Morriconi et al. 2002), and the higher RCI value in January was coincident with the gamete maturation. For M and GMS, no significant changes in mass were observed among the year.

The seasonal biochemical analysis of the FV group showed low values of lipid content in November with an increased level in summer season. We suggest that the energetic variations in FV observed previously (kJ/g AFDW, Lomovasky et al. 2001) could principally be related to the lipid content variations produced by gamete emission in November and gamete maturation in summer season (Morriconi et al. 2002). Similar characteristics were found in *Glycymeris glycymeris* from South Brittany, France (Galap et al. 1997), *Macoma balthica* (Beukema & De Bruin 1977), and *Mytilus edulis* from Dutch Wadden Sea (Pieters et al. 1980, Zandee et al. 1980). The reproductive cycle of *E. exalbida* (Morriconi et al. 2002) showed the presence of mature gonads (60–100%) throughout the major part of the year in both sexes, corresponding with the high levels of lipid content in FV over the year, which has been observed in this study.

Glycogen is the major carbohydrate stored in bivalves (Beukema 1997). However, small amounts of free sugars are always present as well (Whyte & Englar 1982). The glycogen content for FV, M, and GMS found in *E. exalbida* was comparatively lower than the other components (0.03% to 4.7% AFDW), in contrast with other studies in bivalves where high values occurred (31.9% to 48.4%; Giese 1966, Paez-Osuna et al. 1993). Nevertheless, scarce glycogen stored in another burrowing bivalve, *Ensis siliqua*, has been observed (Martinez et al. 1997).

Under conditions of food scarcity, it has been suggested that glycogen from muscular tissues acts as the primary energy reservoir for the formation of gametes in bivalves, such as *Glycymeris glycymeris* (Galap et al. 1997). A reduction of this reserve in storage organs is also commonly correlated with an increase in gonadal lipids (Fernandez-Reiriz et al. 1996, Mann 1979). In the adductor muscle of *E. exalbida*, glycogen content increased during the spawning event (November, in males) and the gamete maturation (summer, males and females) and decreased in the rest of the year, suggesting that glycogen is used in these months but in a very low proportion (<3.3%). Thus, these changes had not been detected in a direct calorimetric analysis (Lomovasky et al. 2001). Therefore, the adductor muscle in *E. exalbida* does not have glycogen storage functions for energy reserves in contrast with previous reports for several bivalves such as scallops (Ansell 1974b, Martínez 1991, Robinson et al. 1981, Sundet & Vahl 1981, Villalaz 1994), mussels (Bayne et al. 1983, Lowe et al. 1982), and oysters (Fernandez Castro & Vido de Mattio 1987).

In FV, the glycogen content was higher in September and January, and a similar tendency for lipid content was observed. The positive correlation between the proportions of carbohydrates and lipids seems to be the rule rather than the exceptions (Beukema 1997). As described above for M, the glycogen content for FV and GMS showed the lowest values along the year, suggesting that this component did not have an important function as substrate for energy reserves in this species.

Alternatively, proteins may be an energy reserve in adult bivalves, particularly during gametogenesis (Beninger & Lucas 1984, Galap et al. 1997). In *E. exalbida*, a higher level of protein content was observed in winter in all tissues, with other increase during the spawning event (November) in FV and in November and January in GMS. In the adductor muscle, with the exception of June, the protein content was approximately constant during the

rest of the year. These results suggest that all these tissues could be involved in the storage of proteins in winter and which are thought to play a role in the gamete maturation. A higher level of protein content in winter has also been observed in digestive gland and gonad of *Spondylus leucacanthus* from the Gulf of California (Rodríguez-Astudillo et al. 2002). It seems therefore that in *E. exalbida*, proteins may be the more important component stored.

The energetically convenient degradation of glycogen has been studied in several species, such as *Mytilus edulis* (De Zwaan & Eertman 1996), *Scapharca inaequivalvis*, and *Venus gallina* (Brooks et al. 1991), related to the type of metabolic pathway used during environmental anaerobiosis when the metabolic rate is strongly suppressed compared with the aerobic resting rate (De Zwaan & Eertman 1996). *E. exalbida* is a subtidal, Sub-Antarctic species whose cold-waters habitat provides it with oxygen. Emerision and anoxia-adapted physiology (De Zwaan & Eertman 1996) may not be related to these species. The protein seems to be its only alternative resource of energy under conditions of food scarcity. However, it cannot be certain without further studies and proper investigation about the possible advantage of using protein as an energy reserve and the mechanisms of regulation (e.g., anti-freezing proteins).

A relationship between the greater availability of phytoplankton (Hernando, pers. comm.), sea temperature, and gamete maturation with a slowed down shell growth has been suggested for this species (Lomovasky et al. 2001, Lomovasky et al. 2002, Morriconi

et al. 2002). Thus, food availability may be an important source of the nutrients required for the gonadal ripening process. Seasonal variation in temperature and the availability of food appear to be closely related to the energy available for growth and reproduction in other bivalve species (Beukema & De Bruin 1977, Griffiths & King 1979, Newell & Branch 1980, Jayabal & Kalyani 1986, MacDonald & Thompson 1986, Mann 1979, Navarro et al. 1989, Smaal et al. 1997, Sukhotin 1992, Zandee et al. 1980). In *E. exalbida* from Ushuaia Bay, shell growth in spring (Lomovasky et al. 2002) occurred during spawning (Morriconi et al. 2002). In summer, the shell growth slowed down, and gamete maturation was found whereby energy was allocated to reproduction rather than to growth. In contrast, juvenile organisms grew up such as in spring and in summer (Lomovasky et al. 2002). The differences detected between juvenile and adult organisms could be related to the energy partition between growth and reproduction.

SEPARATION OF RECENTLY SETTLED MANILA CLAMS, *TAPES PHILIPPINARUM* (A. ADAMS AND REEVE, 1850), FROM THREE SEDIMENT TYPES USING SUCROSE DENSITY SOLUTION

DAPHNE M. MUNROE,¹* DOUG BRIGHT² AND SCOTT MCKINLEY¹

ABSTRACT Thorough study of the life history of important fishery and aquaculture shellfish species is essential for the most appropriate management and development of the resource. The early juvenile life stages of wild intertidal clam populations are difficult to study because of their existence in sediments of similar size and color to the animal. Here, we test the efficacy of methods for separation of recently settled Manila clams (*Tapes philippinarum*) from different types of intertidal sediments using density. Three aquaria were set up with sterilized sediments of each of the three sediment types—cobble/sand/shell, cobble/mud, mud/sand—resulting in nine aquaria total for the experiment. Each tank was filled with filtered, sterilized sea water; the water was heated to 20 °C and aerated. Competent *T. philippinarum* larvae were added to each tank at a known density and were allowed to metamorphose and settle. Aquaria were then drained, and four sediment samples were taken from each aquarium for evaluation of number of juvenile clams present. Samples were wet-sieved to isolate the size fraction from 125 to 500 µm, and then this size fraction was settled through high-density (1.9 g/mL) sucrose solution to separate stained clams from sediments. The average numbers of clams counted per sample for each sediment type were 57.9 (SD = 37.1) for mud/sand, 60.0 (SD = 36.1) for cobble/sand/shell, and 53.1 (SD = 39.6) for cobble/mud. The average number of clams expected per sample based on the number of larvae added to each tank was 58.8 for all three sediment types. Statistical analysis revealed no significant difference between the mean number of clams per sample and the expected value of 58.8 for all three sediment types. Therefore, these results indicate that the methods used here can be used to extract rapidly recently settled Manila clams from all sediment types with a high degree of accuracy.

KEY WORDS: density separation, juvenile clams, sampling, sucrose, *Tapes philippinarum*

INTRODUCTION

The Manila clam (*Tapes philippinarum*, A. Adams and Reeve, 1850) is of major importance to both the wild fishery and aquaculture industry worldwide. In British Columbia, Canada, this species is non-native and is thought to have been introduced along with oyster seed from Japan in the 1930s (Bourne 1982). Since its introduction, *T. philippinarum* has become a very important species economically and is the basis of the current clam culture industry (Jones et al. 1993). The conditions in British Columbia are favorable for the Manila clam, and it has become well established throughout the southern coastline (Quayle 1974).

In the general bivalve life cycle, a pelagic larval stage is followed by metamorphosis, during which the swimming organ or velum is lost, and the bivalve transforms into the benthic or epibenthic juvenile form, depending on the species. The postmetamorphic juvenile stage of the Manila clam is found in the upper layers of the sediment; however, sampling juveniles from these sediments presents many problems because of the similar coloration and size of the clams and fine sediments. Consequently, very few studies have focused on this life stage. When sampling has been carried out and early juveniles in the sediment are counted (Glock 1978, Jones 1974, Williams 1980), the work is extremely time-consuming and prone to error. Rarely, however, is reference made in published studies of bivalve settlement and early life-stage ecology to the accuracy of the sorting and counting methods involved. A simple, consistent, and effective method for separation of postsettlement bivalves from the sediments would allow for more studies to be carried out and more insight into the recruitment patterns of the Manila clam and other valuable clam species to be gained.

The density of juvenile postsettlement clams and cockles was estimated to be 1.036–1.076 g/mL in a study by de Montaudouin (1997) and 1.1 g/mL in a study by Jonsson et al. (1991), whereas minerals are more dense, typically with a specific weight of 2.5 g/mL and higher (Denny 1993). Density gradients of silica sols have been used in many studies to separate lighter meiofauna from higher density sediment fractions (Burgess 2001, Nichols 1979, Schwinghamer 1981). It has been shown that high-density sucrose solutions can also be used to separate meiofauna from muddy organic sediment (Heip et al. 1974). The technique explored herein involves wet sieving to isolate the size fraction of the sediment containing the bivalves, then allowing that size fraction to settle through a high-density sucrose solution (1.9 g/mL) to isolate the meiofauna and allow for easier counting of the bivalves. This technique will be tested using three different sediment types to determine the efficacy of the method with various sediments.

The clam juveniles would be expected to float in a solution with a density of 1.9 g/mL. However, the high concentration of sucrose increases the osmotic pressure on the animal cells causing them to dehydrate, thereby increasing the density of the animals and causing them to sink (Bowen et al. 1972, Price et al. 1978). Although the juveniles become more dense and sink, they sink slowly in relation to the higher density mineral components of the sample and are found in the top layer of the sediment once it has settled out. This process of isopycnic sedimentation at one solute density to separate particles of different densities is called "rho spectrometry" by Price et al. (1977).

MATERIALS AND METHODS

Three different sediment types were obtained from intertidal beaches north of Nanaimo, British Columbia. Nine tanks were prepared with each of the three different sediment types (treatments) randomly assigned to three tanks per sediment type. The

*Corresponding author. E-mail: dmmunroe@interchang.ubc.ca

sediment types were cobble/mud, cobble/sand/shell and mud/sand according to their properties, and a subsample (approximately 20 cm³) of each sediment type was analyzed for grain size components by wet sieving using methods adapted from Komar (1998). Organic material was not removed prior to wet sieving. Briefly, the sediment was wet-sieved, dried at 60°C (Boyd & Tucker 1992) for 30 min, and weighed.

Sediments to be used in the experiment were autoclaved prior to placement in each aquarium. Each aquarium was filled to a depth of 5 cm (surface area of each tank was 800 cm²) with the assigned sediment type, and then filled with 15 L seawater (filtered to 1 µm and sterilized with UV radiation). All aquaria were aerated and warmed to 20°C before addition of competent, hatchery-reared Manila clam larvae. A total of 2400 clams were added to each of the nine tanks.

Tanks were maintained at 20°C and clams were fed a combination of 50:50 *Chaetoceros muellerii* and *Isochrysis spp* (Tahitian strain) at a combined concentration of 20,000–30,000 cells/mL (Jones et al. 1993). Clams were left in the tanks for 11 days to settle and metamorphose. The tanks were then drained to simulate low-tide sampling conditions, and core samples of the sediment were taken. Four sediment cores were taken from each of the nine tanks (36 samples total). A small corer made of PVC pipe (5 cm internal diameter) was inserted 1 cm into the sediment, and a thin metal lid was slid under the pipe to prevent the sediment from falling out. Samples were placed in a plastic sample bag, labeled, and frozen for later counting. Freezing was chosen as a method of sample preservation to ensure consistency between laboratory methods and field methods that have been used for a parallel study.

For enumeration, samples were thawed then placed in 0.01% phloxine B dye for at least 20 min (Williams 1978). Samples were then washed through a series of sieves; the fraction of sediment from 125 to 500 µm was placed into a high-density sucrose solution (1.9 g/mL) in 30-mL test tubes. The test tubes were inverted to mix the sediments, to avoid particle-particle interactions (Price et al. 1977), then left to settle out by gravity (minimum of 25 min). The top layer of sediment was pipetted off the surface of the settled sediments in the test tube. The amount of sediment pipetted off the top was approximately 1–2 mL, which is less than 10% of the original core sample volume. The number of clams in each sample was counted under a dissecting microscope at 60× magnification. Statistical analysis of variance was calculated using JMP statistical software.

RESULTS

The grain size for each sediment type is shown below in Table 1. The cobble/mud sediment contained the largest fraction of the

>2000-µm size category with 82% by weight. The cobble/sand/shell also contained mostly >2000-µm-sized components; however, it should be noted that in this case, over half of this size category was composed of broken shell whereas the >2000-µm fraction in the cobble/mud was entirely small cobble. The mud/sand sediment was mostly composed of medium sand (70% dry weight); with coarse sand and fine sand making up another 18% dry weight. The components >2000 µm were only broken shell in the mud/sand sediment.

Two thousand four hundred clams were added to each tank, and each tank had a sediment surface area of 800 cm²; therefore, the expected average density of clams in each tank was 3 clams/cm². The surface area of each core was 19.7 cm², so the expected average number of clams per core was 58.8. The means and 95% confidence limits for number of clams recovered from coring the three sediment types is shown in Figure 1. Comparison of the mean numbers of clams per core among the three sediment types was done to test if all means were equal regardless of sediment type. The mean values for clams per core were 60.0 for cobble/sand/shell, 53.1 for cobble/mud, and 57.9 for mud/sand. Based on analysis of variance, there was no significant difference in the number of juvenile clams recovered from each of the different sediment types and the expected value 58.8 ($n = 3$, probability ranged from 0.63 to 0.94). Nor was there a significant difference between treatments ($n = 3$, probability = 0.90). Individual *t*-tests were also run to determine if the recovery of clams from coring of any of the experimental units (nine tanks × three treatments) departed significantly from the expected value based on larval seeding density. There was no statistically significant difference between the observed and expected values for any of the experimental units ($n = 4$, probability ranged from 0.30 to 0.75).

DISCUSSION

Analysis of grain size components (Table 1) shows that there were large differences between the compositions of the three sediment types used in this experiment. This was important because we were testing the accuracy of the sampling methods for extraction and counting of postsettlement juveniles in different types of sediments. For example, the mud/sand sediment was composed of 70% medium sand, which means 70% of the entire sample was the same size class in which the bivalves are found. This has the potential to lead to difficulty and inaccuracy in extraction of the clams from this large sediment fraction. In this experiment, no difficulties were encountered: The numbers of clams counted per core did not differ in the three types of sediment. Furthermore, for all three sediment types, the number of clams counted in each sample did

TABLE 1.
Grain size components, percentage by dry weight, of each sediment type.

Size Class	Size Range (µm)	% Overall Weight		
		Cobble/Mud	Cobble/Sand/Shell	Mud/Sand
Shell	(>2000)	—	43	4
Granule+	(>2000)	82	30	—
Very coarse sand	(1000–2000)	3	8	3
Coarse sand	(500–1000)	4	7	11
Medium sand	(125–500)	7	9	70
Fine sand	(75–125)	2	2	7
Silt	(<75)	2	1	5

The size category >2000 µm contains both granule+ and broken shell.

Figure 1. Means and 95% confidence limits for numbers of clams per sample for the three sediment types. The dashed line indicates the expected number of clams per sample (58.8) based on the number of larvae placed in each tank. ($n = 3$ for each treatment).

not differ from the value expected per sample based on the number of clams initially placed in tanks. This means that with this method, there was an estimated 100% recovery of bivalves from sediment regardless of sediment type.

Individual tanks within each sediment type were tested to ensure that mean numbers of clams counted per sample did not differ statistically from one tank to the next. Large standard errors were seen in data from some individual tanks. These were overcome when all samples of each sediment type were analyzed together. This may be interpreted as a result of the patchy settlement of clam larvae (Williams 1980), especially in coarser and heterogeneous substrates, and implies that the sampling effort may need to be increased for such sediment types.

The recovery of 100% of the bivalves that were placed in tanks also suggests 100% survival from the time of introduction of the larvae to the time of recovery of postsettlement clams. Survival rates for *T. philippinarum* in a hatchery generally vary from 50–90% depending on larval quality (Utting & Spencer 1991). The recovery of an estimated 100% of added larvae (had the entire sediment surface been sampled) is probably due to the relatively short duration of the study. Some of the postsettlement clams, in fact, may have been nonviable or dead at the time of sampling, but freezing and subsequent staining would not distinguish recently deceased clams from live ones. In other circumstances, it might be expected that some mortality would occur prior to settlement, so a failure to account for 100% of the introduced larvae might not be attributable to the sorting techniques in other studies.

Separation and counting of live clams prior to freezing was not attempted, leaving some question about whether separation as described herein would be equally effective for live specimens or those preserved using other methods such as formalin fixation. Schwinghamer (1981) conducted tests on live separation of benthos from mud and sediments using centrifugation in sorbitol

and Percoll and found it to be an effective separation method that allowed for proper identification and observation of sampled benthos.

In a study by Burgess (2001), density separation of meiofauna from sediment was carried out using Ludox. Sediment samples were mixed with Ludox, then centrifuged to separate the meiofauna. Using this method, Burgess was able to recover 95.9% of the bivalves in the sample. Jonge and Bouwman (1977) also found the use of density separation of nematodes and copepods from sediment and detritus to be more effective and accurate than hand-sorting decantation methods. Both Burgess (2001) and Jonge and Bouwman (1977) note that a potential shortcoming of the density separation method is that animals may attach to sediments and therefore sink with them. Postmetamorphic bivalve juveniles have the ability to attach to larger sediments using a byssus. In this study, the sediment fractions larger than 500 μm were not examined to look for attached juveniles; however, recovery was estimated at 100% in the size fraction examined, so few if any clams were likely to have been found in larger fractions. It is possible that if there were any clams attached to sediments by byssal threads, the threads were released when the sediment samples were frozen.

The use of the sucrose-density separation method described here is effective for counting newly settled juvenile clams from sediment. The use of the high-density sucrose solution to isolate the lower density animals increases sampling efficiency by decreasing the time to sort through sediment. Decreasing the time to sort increases sampling accuracy because less physical and psychologic variance is introduced (Price et al. 1977). This decrease in sorting time would be especially important for sediments like the mud/sand sediment used here, where sieving would result in retention of the majority of the sediments along with the bivalves and, thus, hand sorting and counting would be quite tedious and prone to error.

These results show that these methods can be used in the field with the confidence to count recently settled clams in sediment samples involving a variety of sediment types. This would be useful in the assessment of farming techniques and questions of industry sustainability and environmental protection. Juvenile density estimates are important in the understanding of settlement patterns and early mobility in this economically important species. More generally, such studies are crucial to the understanding of bivalve larval ecology, demographics, and environmental/climatic factors that control recruitment, as well as invasion rates of exotic bivalves.

ACKNOWLEDGMENTS

We would like to acknowledge the generous donation of lab space and larvae by the Center for Shellfish Research at Malaspina University-College; particularly the help of Dr. Bill Pennell for his guidance and enthusiasm, Gord Edmondson for help with equipment preparation, and Jenny Dawson-Coates for help with algal rearing and feeding. Also, the authors thank Terri Sutherland for her helpful comments.

ACETYLCHOLINE AND SEROTONIN INDUCE LARVAL METAMORPHOSIS OF THE JAPANESE SHORT-NECK CLAM *RUDITAPES PHILIPPINARUM*

ABSTRACT The effects of neuroactive compounds on larval metamorphosis of the Japanese short-neck clam *Ruditapes philippinarum* (Heterodonta, Veneridae) were investigated by exposing pediveligers to acetylcholine, serotonin, epinephrine, norepinephrine, dopamine, L-3,4-dihydroxyphenylalanine (L-DOPA), carbamylcholine, and succinylcholine at concentrations of 1, 10, and 100 μ M. Larval metamorphosis with 100 μ M serotonin was 80.7%, and that with 10 μ M and 100 μ M acetylcholine was 92.9% and 70.6%, respectively. No significant differences were observed in the induction activities of epinephrine (35.1–36.1%), L-norepinephrine (2.1–20.3%), L-DOPA (6.4–15.8%), and nontreated groups (0–5.6%). Dopamine showed no inducing activity. Treatment with 100 μ M carbamylcholine induced 37.6% of metamorphosis in 23-day-old larvae. Larval metamorphosis rate increased significantly with exposure time when treated with acetylcholine, carbamylcholine, and serotonin. Low postlarval survivorship after treatments might not be related to toxicity of chemicals but due to an energy deficiency after an accelerated completion of metamorphosis in neurochemically stimulated larvae. The effectiveness of inducer drugs was observed to be age-dependent. Nineteen-day-old larvae reacted less than 23-day-old ones from the same cohort. Larvae of *R. philippinarum* responded differently to neurotransmitters from bivalves of the subclass Pterimorpha (i.e., Ostreidae, Pectinidae, Mytilidae) which are more sensitive to catecholamines and L-DOPA. This difference suggests that the mechanisms triggering metamorphosis may differ among bivalve groups.

INTRODUCTION

Many marine benthic invertebrates produce planktonic larvae. At the end of the planktonic period, larvae respond to complex environmental and biologic stimuli leading to settlement and metamorphosis, allowing the onset of juvenile and adult benthic life forms. This transition is modulated by chemical cues of various biologic origins (Hadfield & Paul 2001). Such cues bind to specific receptors located in the larval neural tissues, triggering metabolic pathways resulting in the behavioral and morphologic changes typical of the metamorphosis process (Burke 1983, Sarojini et al. 1999). Neurotransmitters, their precursors, or similar molecules have been reported to mimic the natural chemical cues and are known to trigger larval settlement and metamorphosis in a variety of marine invertebrates (Hadfield 1984, Morse 1985, Morse 1990, Pires & Hadfield 1991, Okamoto et al. 1995). In bivalves, catecholamines and L-3,4-dihydroxyphenylalanine (L-DOPA) were described as highly effective inducers in *Mytilus edulis* (Cooper 1982), *Crassostrea virginica* (Coon et al. 1986), *Ostrea edulis* and *C. gigas* (Shpigel et al. 1989), *C. belcheri* (Tan & Wong 1995), *Pecten maximus* (Chevolot et al. 1991), and *M. galloprovincialis* (Satuito et al. 1999). Furthermore, acetylcholine was reported as a settlement inducer for *C. gigas* (Beiras & Widdows 1995) and gamma aminobutyric acid increased the settlement rate of *Pinctada margaritifera* (Doroudi & Southgate 2002). Despite their ecological and economical importance, few studies have assessed larval settlement and metamorphosis of clams; soft bottom burrowers like *Mercenaria mercenaria* (Bachelet et al. 1992, Woodin et al. 1995), *Mulinia lateralis* (Luckenbach 1984, Grassle et al. 1992), *Spisula solidissima* (Snelgrove et al. 1998), and *Mya arenaria* (Snelgrove et al. 1999) have been studied for settlement and habitat selection in terms of hydrodynamics. However, biologic and

chemical regulation of these processes is largely unknown in clams. We investigated the effects of neuroactive compounds on larval metamorphosis of *Ruditapes philippinarum*, focusing on a search for highly effective inducers, the postmetamorphic survivorship, and a larval age dependent response. The Japanese short-neck clam is an important commercial resource that sustains fisheries and aquaculture. Recently, disease outbreaks (Hamaguchi et al. 1998, Allam et al. 2000, Renault et al. 2001) along with seasonal (Calvez & Guillou 1998) and environmental fluctuations (Ishii et al. 2001) have diminished wild and farmed populations of this clam. Effective chemicals for induction of larval metamorphosis may improve aquaculture practices and add to our understanding of factors controlling settlement and metamorphosis in clams.

MATERIALS AND METHODS

Larval Cultures

Groups of the Japanese short-neck clam *R. philippinarum* (total shell length: 27.5 ± 2.3 mm, $n = 40$) were collected during reproductive seasons (May and October 2001) from Hamana Bay, Japan ($34^{\circ}41'33''N$, $137^{\circ}35'58''E$). Spawning was induced by combining cycles of exposure to cool air (Satuito et al. 1994), immersion in a sperm solution (Loosanoff & Davis 1963) obtained by stripping of 1–2 mature males, and thermal stimulation (Toba et al. 1994). Finally, the clams were kept individually in 50-mL beakers filled with 1- μ m filtered seawater (FSW) at 20°C for spawning. Released ovules were suspended in FSW in a glass container. Similarly, released sperm was collected and suspended. Adding drops of the sperm solution, a mixture of ovules from several female clams was fertilized. Further on, fertilized zygotes were washed with FSW, placed in 1-L beakers containing fresh FSW, and kept undisturbed for embryonic development at 25°C (Toba 1992). Straight-hinge veligers were collected 20 to 24 h after fertilization, washed with GF/F-FSW (Whatman GF/F glass-fiber filters), and placed in 1-L glass containers filled with GF/F-

*Corresponding author. E-mail: anobu@mail.ecc.u-tokyo.ac.jp

FSW under the following conditions: Initial density of 10 larva/mL (Toba et al. 1994), 25°C constant temperature (Toba 1992), and salinity of 29–32 p.s.u. throughout the culture period. Aeration was provided for the larval culture containers through glass Pasteur pipettes during the entire culture period. Larval age in days was counted from the first day of larval culture (first straight-hinge veliger). Daily *ad libitum* food ration was given as follows: An initial diet of *Pavlova lutheri* at 3×10^5 cells/mL (final concentration) was provided until day 5, after which a mixture of *Chaetoceros calcitrans* and *Pavlova lutheri* was given at 4×10^5 cells/mL until the culture was finished (Toba et al. 1994). Microalgae for the larval diets were cultured in K medium (Keller & Guillard 1985) at 25°C and constant illumination. Early pediveligers were observed from days 12 to 14 of culture. Pediveliger culture densities were kept at 1.5 larva/mL. Two experiments were carried out with actively swimming pediveligers. Larval survivorship of the cultures used for experiments 1 and 2 was 24.1% and 31.3%, respectively.

Experiment 1: Effects of Neuroactive Compounds on Larval Metamorphosis

Six neuroactive compounds, acetylcholine chloride (Wako Pure Chemical Industries, Ltd), serotonin creatinine sulfate (Wako), epinephrine bitartrate (Research Biochemicals Inc.), L-norepinephrine bitartrate (Wako), dopamine hydrochloride (Wako) and L-DOPA (Wako) were tested at three concentrations (1, 10, and 100 μ M) in triplicate against a control group. Stock solutions were prepared by dissolving in FSW at several folds of the final concentration. Filtered seawater was used for the control group and dilution of chemical compounds. Eight hundred forty-seven 22-day-old pediveligers were distributed at a density of approximately 1–2 larva/mL in 57 10-mL glass beakers containing FSW. The corresponding solution of neuroactive compound was added to adjust the final concentrations to 1, 10, and 100 μ M and final volume to 10 mL in each beaker. Only FSW was added to three of the beakers containing larvae to adjust to the final volume of 10 mL; these were used as control groups. Because oxidation of catechols was expected to occur in seawater, larvae were placed into fresh FSW and newly prepared chemical solutions every 12 h. This procedure was applied to all treatments, subjecting the larvae to the same conditions. Onset of metamorphosis was monitored after 24 and 48 h of exposure. The criteria to determine whether a larva had metamorphosed were by visual detection of postlarval shell growth, complete loss of velum, and observation of the gill rudiment activity using a stereomicroscope and an inverted microscope. Metamorphosed larvae are referred to as postlarvae. After 48 h exposure to the chemicals, larvae and postlarvae were washed, placed in neuroactive-compound-free FSW, and maintained for 24 h to monitor post-treatment survivorship and other effects such as late metamorphosis response. Larvae were not fed during the assay. The experiment was run at 22°C in a dark, temperature-controlled room at the Fisheries Laboratory of the University of Tokyo, Hamana Bay, in June 2001.

Experiment 2: Effects of Larval Age and Neuroactive Compounds on Larval Metamorphosis

Based on the results obtained in experiment 1, this assay was conducted to evaluate exclusively the cholinergic agonists acetylcholine chloride, carbamylcholine chloride (Nacalai Tesque Inc.), and succinylcholine chloride (Wako), and serotonin creatinine sulfate on the metamorphosis of a cohort of larvae of three age

groups, 19, 21, and 23 days old. This assay was run in triplicate against a control group. The concentrations of chemicals were adjusted to 1, 10, and 100 μ M and an exposure time of 48 h. A sample of pediveligers was taken from the culture and subjected to the induction assay; remaining siblings were kept in culture until the indicated ages at a density of approximately 1.5 larva/mL and with aeration to avoid settlement. Five hundred fifty 19-day-old larvae and 437 and 339 21- and 23-day-old larvae, respectively, were distributed in 10-mL beakers in a similar way as in experiment 1. Larvae were not fed during the assay. Metamorphosis was monitored after 1, 5, 12, 24, 36, and 48 h of exposure. The trials were run in triplicate against triplicate control groups of FSW under the same conditions as in experiment 1.

Data Analysis

The Kolmogorov-Smirnoff test ($\alpha = 0.05$) was used for evaluation of normality. Metamorphosis percentages were analyzed using Kruskal-Wallis analysis of variance (ANOVA) on ranks followed by Dunnett multicomparison ($\alpha = 0.05$). The effect of each chemical on larval metamorphosis was classified as positive when the metamorphosis percentage was higher than the control group and as negative when the metamorphosis percentage was equal to or lower than that of the control group. The metamorphosis response at 24 and 48 h in each treatment was compared using a *t*-test ($\alpha = 0.05$). A Kruskal-Wallis ANOVA on ranks followed by a Dunnett multicomparison test ($\alpha = 0.05$) was used to analyze the postlarval survivorship among compounds and concentrations. A two-way ANOVA followed by a Tukey test ($\alpha = 0.05$) for pairwise comparison was used to assess the effect of larval age on the response to three concentrations of serotonin and choline compounds with the data arcsine square root transformed.

RESULTS

Effects of Neuroactive Compounds on Larval Metamorphosis

Larval metamorphosis of *R. philippinarum* induced by neuroactive compounds varied with concentration. Positive responses were observed for five of the six chemicals tested (Fig. 1). Acetylcholine at 10 μ M showed the highest percentage metamorphosis after 48 h (mean \pm SD $n = 3, 92.9 \pm 12.4\%$) followed by serotonin at 100 μ M ($80.7 \pm 18.0\%$) and acetylcholine at 100 μ M ($70.6 \pm 14.2\%$). Metamorphosis percentages obtained with these treatments were significantly higher than that of the control group ($P < 0.05$). Larvae exposed to either 1 μ M acetylcholine or 1 μ M serotonin did not metamorphose during the 48-h assay period. Positive chemicals showed no differences in induction activities at 24 h and 48 h of exposure ($P > 0.05$), except for acetylcholine at 10 and 100 μ M ($P < 0.001$ and $P = 0.005$, respectively), where the metamorphosis was induced within 24 h. The metamorphosis percentage was significantly increased when larvae were exposed to higher concentrations of acetylcholine ($P = 0.021$) and serotonin ($P = 0.028$). Although epinephrine showed a positive effect, there were no statistical differences between epinephrine and the control group ($P = 0.166$). Larvae of *R. philippinarum* metamorphosed in response to L-norepinephrine and L-DOPA, yet they were less effective, yielding low percentage metamorphosis, and were not significantly different from the control group. Dopamine showed no inductive effect at all concentrations tested after 48 h of

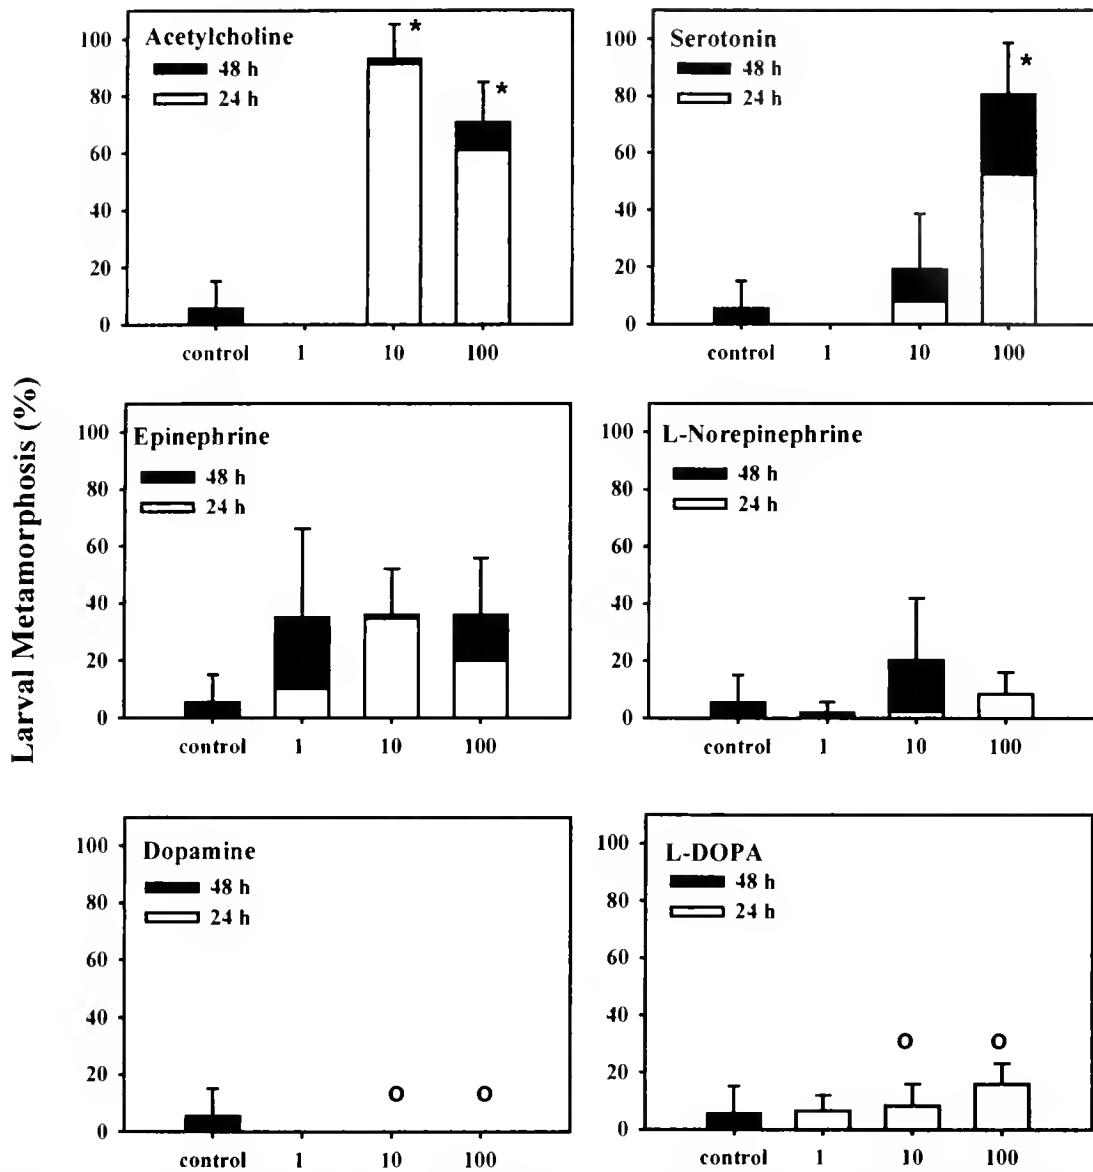

Figure 1. Metamorphosis of *Ruditapes philippinarum* induced by neuroactive compounds. Bars indicated cumulative mean metamorphosis percentage after 24 and 48 h (\pm SD, $n = 3$). Asterisk (*) indicates differences to the control (FSW). Circle (○) indicates 100% larval and postlarval mortalities after 48 h of exposure.

exposure. Larval mortalities were observed when exposed to dopamine and L-DOPA at concentrations of 100 and 10 μ M.

Larvae exposed to the effective chemicals changed their regular swimming pattern, combining crawling and short swimming near the bottom. A progressive extension of the crawling period was observed to be dependent on exposure time. Vela in the pediveligers lost most of their cilia. When there was no movement, we assumed they were metamorphosing, because larvae and postlarvae always crawled before and after metamorphosis; no byssal attachment was observed.

Effects of Neuroactive Compounds on Postlarval Survivorship

After assays, larvae and postlarvae were transferred to fresh FSW to observe post-treatment responses after 24 h. Postlarval survivorships are summarized in Table 1. Variability was observed in the postlarval survival rate after exposure to neurochemicals for 48 h. All postlarvae died after exposure to L-DOPA in all concen-

trations tested. Larvae that did not undergo metamorphosis died in all cases studied, except for the control group and the 1 μ M acetylcholine, 1 μ M serotonin, and 1 μ M dopamine treatments, where remaining pediveligers displayed active swimming or crawling behavior. In these trials, newly metamorphosed larvae were observed (acetylcholine, $4.3 \pm 3.8\%$; serotonin, $14.2 \pm 1.6\%$; and dopamine, $7.8 \pm 6.9\%$) and recorded as post-treatment metamorphosis (Table 1). No significant differences ($P = 0.944$) in postlarval survivorships at the concentrations tested were observed among treatments. This result indicates that concentrations of 1, 10, and 100 μ M of the neurochemicals used for metamorphosis induction may not have affected the postlarval survivorship, except for treatments with L-DOPA at the higher concentrations, which led to 100% postlarval mortalities. The percentage survivorship of postlarvae after the treatments with acetylcholine, serotonin, epinephrine, and L-norepinephrine was not significantly different from that of the control group (100% survival) ($P = 0.062$).

TABLE 1.

Postlarval survivorship of *Ruditapes philippinarum* 24 h after treatment with neurocompounds.

Compounds	1 μ M	10 μ M	100 μ M
Acetylcholine	4.3 \pm 3.8*	5.2 \pm 4.5	30.1 \pm 6.9
Serotonin	14.2 \pm 1.6*	92.2 \pm 7.2	22.0 \pm 11.1
Epinephrine	23.7 \pm 26.7	13.7 \pm 5.2	6.5 \pm 6.7
L-norepinephrine	5.4 \pm 5.1	19.2 \pm 5.4	0
Dopamine	7.8 \pm 6.9*	0	0
L-DOPA	0	0	0

Pediveligers were exposed to neuroactive-compounds solutions for 48 h. Immediately after the induction assay, postlarvae were transferred to FSW for 24 h to observe survivorship. Figures indicate mean survival percentage \pm SE ($n = 3$). Postlarvae of the control group (FSW) exhibited 100% survival.

* Completion of metamorphosis observed 24 h after the chemical treatment (post-treatment metamorphosis).

Effects of Larval Age and Neuroactive Compounds on Larval Metamorphosis

Ruditapes philippinarum pediveligers of the three age groups (19, 21, and 23 days old) from the same cohort showed a distinct metamorphosis rate when exposed to various concentrations of choline derivatives and serotonin (Fig. 2). The highest metamorphosis percentages were obtained when 21-day-old larvae were exposed to 10 μ M serotonin and 23-day-old larvae to 10 and 100 μ M serotonin (mean \pm SD $n = 3$, 71.4 \pm 49.5%, 61.8 \pm 18.6%, and 64.0 \pm 10.3%, respectively), of which only the responses of 23-day-old larvae to 10 and 100 μ M serotonin were significantly higher than the control group ($P < 0.05$). Lower metamorphosis percentages yet significantly different from control groups were observed in 21-day-old larvae treated with 1 and 100 μ M acetylcholine and 100 μ M carbamylcholine ($P < 0.05$). Percentage metamorphosis of 23-day-old larvae treated with acetylcholine 100 μ M was also significant ($P < 0.05$). Among age groups, metamorphosis percentages obtained when exposed to FSW (control group) were not significantly different ($P = 0.089$). The larval age was found to influence significantly larval metamorphosis induced by acetylcholine ($P < 0.001$), carbamylcholine ($P < 0.001$), and serotonin ($P = 0.011$). Younger larvae exhibited the lower response to the chemicals. A significant increase in the percentage metamorphosis was observed when 19-day-old larvae were compared with 23-day-old larvae ($P < 0.05$). Responses of 21- and 23-day-old larvae to acetylcholine, carbamylcholine, and serotonin were not significantly different ($P > 0.05$). Metamorphosis rate did not increase with exposure time when larvae of the 19-day-old group were stimulated with neuroactive compounds ($P = 0.059$, Fig. 3). A significant time-dependent response was observed for larvae of 21-day-old ($P = 0.003$) and 23-day-old ($P < 0.001$) when treated with acetylcholine, carbamylcholine, and serotonin. It should be noted that the onset of metamorphosis was observed after 5-h exposure for 23-day-old larvae, which subsequently metamorphosed within 24 h. Percentage metamorphosis did not significantly increase for concentrations of serotonin ($P = 0.331$), acetylcholine ($P = 0.123$), and carbamylcholine ($P = 0.175$). Acetylcholine and carbamylcholine were effective at lower and higher concentrations. Similar trends were observed for acetylcholine in experiment 1. Serotonin was more effective at higher concentra-

tions for older larvae. Effectiveness of serotonin at the highest concentration tested was observed in experiment 1 as well. However, the percentage metamorphosis of 21-day-old larvae when exposed to 100 μ M serotonin was similar to that of the control group ($P = 0.269$). This outcome was in contrast to the effectiveness of 100 μ M serotonin observed in experiment 1 and later with older sibling larvae. Succinylcholine exhibited the least effect; no significant differences among age groups and doses were observed (19-day-old, $P = 0.392$; 21-day-old, $P = 0.392$; 23-day-old, $P = 0.278$).

DISCUSSION

Effects of Neuroactive Compounds on Larval Metamorphosis

Our investigation demonstrated that the neuroactive compounds serotonin and acetylcholine induced larval metamorphosis of the Japanese short-neck clam *R. philippinarum*. We first tried to identify highly effective inducer neuroactive compounds in terms of high postlarval yield. We assessed different types of neuroactive compounds: the choline derivative acetylcholine, the indolamine serotonin, and the catechols epinephrine, L-norepinephrine, dopamine, and L-DOPA. Among the compounds tested, acetylcholine (10 and 100 μ M) and serotonin (100 μ M) exhibited the highest inducing activity on larval metamorphosis. Soon after exposure to these chemicals, pediveligers exhibited a behavioral shift from swimming to crawling actively on the bottom. Most larvae completed metamorphosis in 48 h. In contrast, only weak activity of serotonin at the same concentration ranges was reported for *Mytilus galloprovincialis* (Satuito et al. 1999), *Crassostrea gigas* (Beiras & Widdows 1995), and *Patinopecten yessoensis* (Kingzett et al. 1990). Acetylcholine was previously reported to be ineffective for *M. galloprovincialis* (Satuito et al. 1999), but an "active" inducer for *C. gigas*, though only 20–40% of larvae metamorphosed (Beiras & Widdows 1995). Recently, it was reported that acetylcholine induced <40% metamorphosis in *Mytilus edulis* larvae (Dobretsov & Qian 2003). Interestingly, the catecholamines, epinephrine and norepinephrine, and L-DOPA were not effective inducers of larval metamorphosis of *R. philippinarum*. The ineffectiveness of epinephrine and norepinephrine was also observed for the Venus clam *Ruditapes largillierii* (Kent et al. 1999). Thus, clam species of the genus *Ruditapes* (subclass Heterodonta) seem to exhibit a different response to neuroactive compounds than bivalves in the subclass Pterimorphia (i.e., Ostreidae, Pectinidae, Mytilidae), which have routinely been induced to metamorphose by epinephrine, norepinephrine, or L-DOPA. Our results suggest that acetylcholine and serotonin may play roles in the metamorphosis of *R. philippinarum*. Regardless of the internal regulatory mechanism, solutions of these neuroactive compounds accelerated metamorphogenic changes in *R. philippinarum* pediveligers. In the absence of an appropriate chemical inducer, metamorphosis did occur, but at a slower rate, as was observed in the pediveligers incubated in FSW.

Although there are differences in chemicals capable of inducing larval metamorphosis in *R. philippinarum*, behavioral and morphologic changes associated with the end of larval life were rather similar to bivalves reported in other studies. *R. philippinarum* exhibited a change of the typical pediveliger swimming behavior; the larva showed alternating cycles of near-bottom swimming and crawling followed by only crawling on the substrate until the onset of metamorphosis, where no motion was observed until the completion of the final anatomic changes of metamorphosis. How-

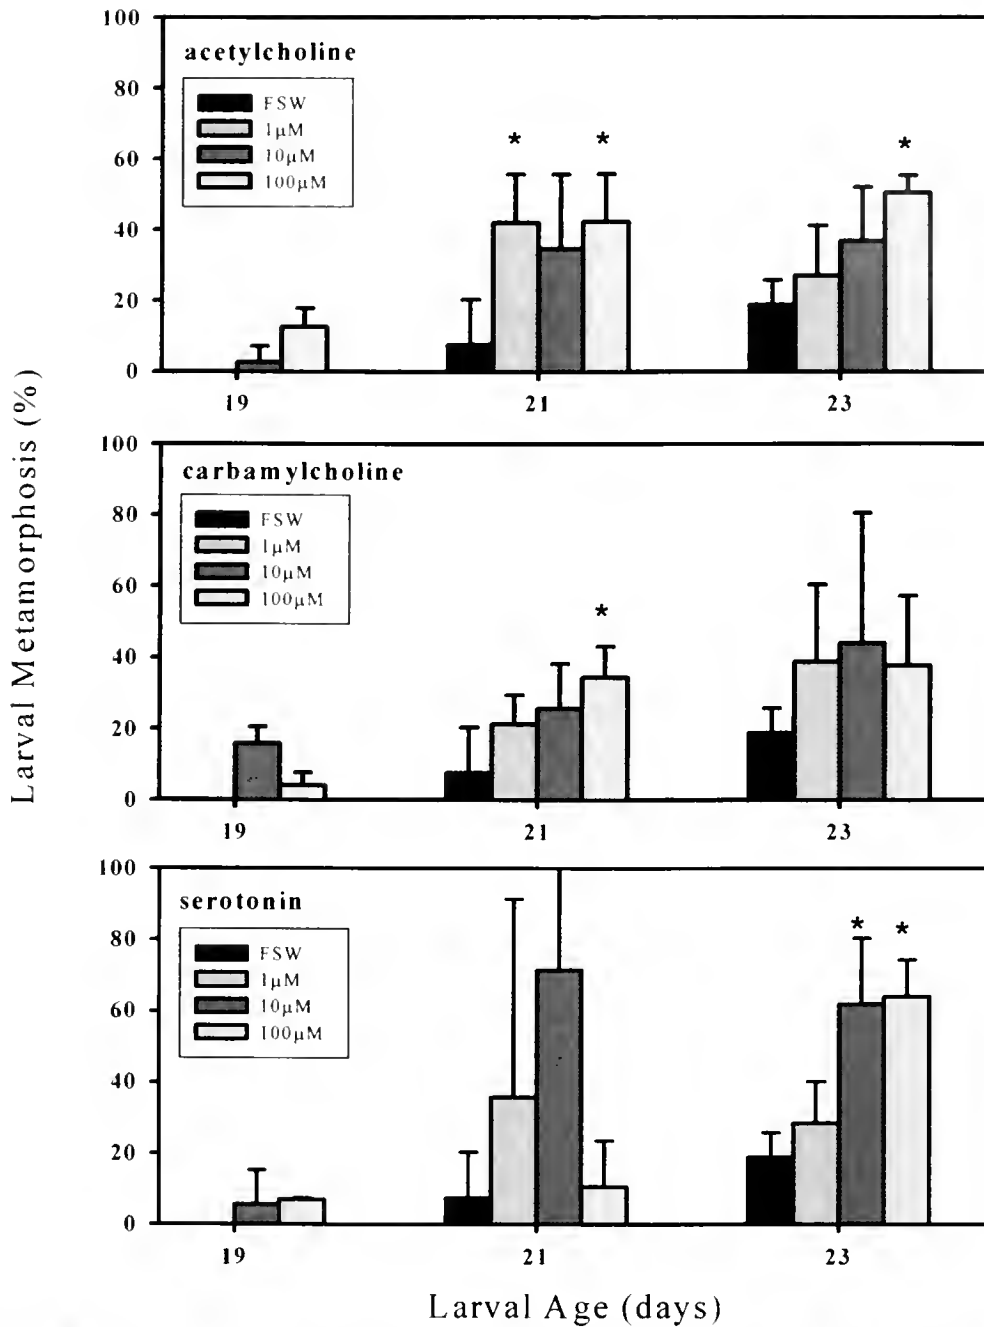

Figure 2. Metamorphosis percentages at three larval ages of a cohort of *Ruditapes philippinarum* when exposed to acetylcholine, carbamylcholine, and serotonin for 48 h. Bars indicate mean \pm SD ($n = 3$). Asterisk (*) indicates significant differences to the control groups (FSW) ($P < 0.05$). Metamorphosis increased significantly with the larval age ($P < 0.05$). 19-day-old larvae were compared to 21- and 23-day-old larvae. Metamorphosis of 21- and 23-day old larvae were similar ($P > 0.05$).

ever, *R. philippinarum* pediveligers do not attach to the substrate prior to metamorphosis; they do not secrete a cementing or fixing substance unlike oysters (Cranfield 1973), mussels (Eckroat & Steele 1993), and scallops (Benninger & Le Pennec 1991, Tapia et al. 1993).

Effects of Neuroactive Compounds on Postlarval Survivorship

Postlarvae of *R. philippinarum* obtained by treatment with neuroactive compounds had a very variable and low survival rate after

treatments. We observed that the survival rate did not differ significantly among all concentrations, but it did differ among compounds. Dopamine and L-DOPA at higher concentrations appeared to be toxic after 48 h of exposure. When treated with acetylcholine, serotonin, epinephrine, and L-norepinephrine, the postlarval survival rate was low. The control group exhibited a remarkable survivorship of 100%. In contrast, with treatments of acetylcholine and serotonin, a much higher percentage of metamorphosed larvae was observed within 48 h of exposure, yet surprisingly, a high

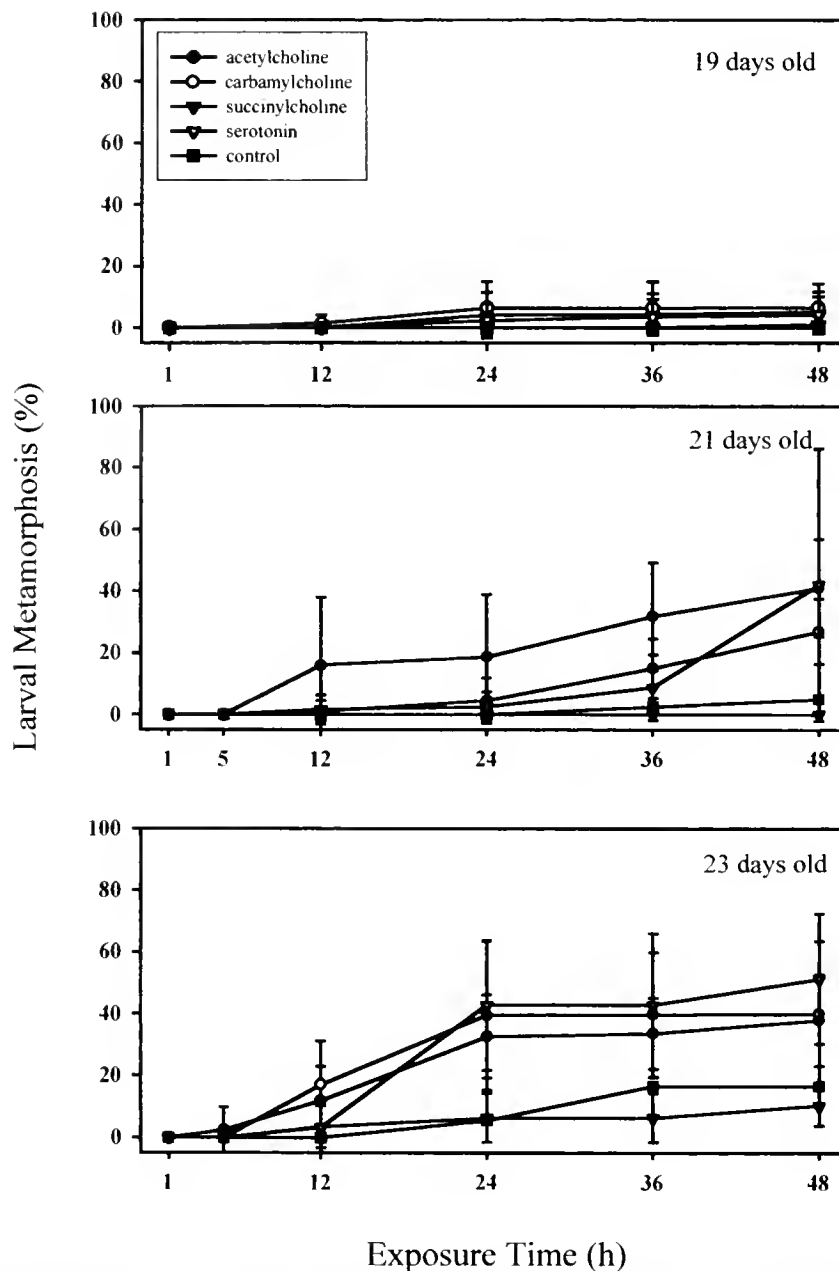

Figure 3. Time-dependent response of a cohort of *Ruditapes phillipinarum* larvae to neuroactive compounds. Plots indicate cumulative mean percentage metamorphosis (\pm SD, $n = 9$).

proportion of those postlarvae was not able to survive. Primarily, this low survival rate seems to be related to the chemical treatment (i.e., a toxicity degree). However, taking into account that our assay was carried out under no feeding conditions—exposing the individuals to over 72 h of starvation—the low postmetamorphosis survivorship may be due to an energy deficiency rather than toxicity of neuroactive compounds. Treatments of effective inducers such as acetylcholine and serotonin may have intervened the neural pathways needed to trigger metamorphosis, accelerating the process (Hadfield 2000). Consequently, more larvae underwent metamorphosis prior than they could replete metabolic reserves to endure metamorphosis. This may explain our low postlarval survival rate under nonfeeding conditions. However, the fact that 100% survival of non-fed “spontaneously” metamorphosed post-

larvae in the control groups impedes reconciling of our results. For this reason, our arguments need to be addressed in future studies. Mortality rates after induction of metamorphosis by chemicals have also been reported for oysters. Haws et al. (1993), in the oysters *C. gigas* and *C. virginica*, found an increment of mortality due to a depletion of lipids, carbohydrates, and proteins 36 h after larval metamorphosis induced by epinephrine. Interestingly, Shpigel et al. (1989) reported no negative effects of epinephrine on the survival rate of *O. edulis* cultchless spats fed daily with a mixed microalgae diet. Consequently, food availability after metamorphosis may be one of the main factors determining postlarval survivorship. Therefore, effective neuroactive compounds may serve as postlarval yield enhancers only when the food supply after the treatment is sufficient.

Effects of Larval Age and Neuroactive Compounds on Larval Metamorphosis

We demonstrated that larval age had a significant effect on larval response to effective neuroactive compounds. The effectiveness of acetylcholine and serotonin was low in 19-day-old larvae treated for 48 h. Sibling larvae only 2 days older exhibited a significantly enhanced response to the same chemicals. Among the older larvae assayed in our experiments (21 and 23 days old), the responses to the effective neuroactive compounds were similar. Thus, it seems that effective neuroactive compounds such as serotonin and acetylcholine have the same effect on metamorphosis of older larvae. Taken together, in the results of both experiments we find support to conclude that *R. philippinarum* pediveligers older than 21 days become competent to metamorphosis in response to acetylcholine and serotonin. The same pattern was observed when larvae were exposed to carbamylcholine, an acetylcholine receptor agonist. This compound exhibited a similar activity-increment to that observed with acetylcholine in the same range of concentrations, though it was less effective. These findings along with those obtained in experiment I may suggest that

acetylcholinergic and serotonergic neural pathways play roles in triggering metamorphosis in *R. philippinarum*. The observed age-dependency of the clam's responsiveness to chemical-inducing stimuli may suggest the development of a sensory system at the end of the pediveliger stage for the recognition of specific cues for settlement and metamorphosis (Hirata & Hadfield 1986, Pawlik 1992, Hadfield et al. 2000). We assumed that the effective neuroactive compounds stimulated those receptors directly involved in metamorphosis regulation of the short-neck clam. A great deal of variability in the larval responses to neuroactive compounds was evident, which may be explained in part by the variability in the degree of development among individuals in the cohort. The effectiveness of serotonin and acetylcholine at various larval ages suggests that these compounds could be used to synchronize several larval cohorts for postlarval yield. These may have useful applications in aquaculture production as well as in metamorphosis studies of the Japanese short-neck clams.

ABSTRACT Manila clams (*Venerupis philippinarum*, A. Adams and Reeve 1850) are an important aquaculture species on the west coast of North America and are also cultured in Europe, Asia, and other locations. Clams cultured on the west coast of North America are free of *Perkinsus* sp. infections, while clams from certain Asian and European sources are infected. Infection in Korean Manila clams is reportedly associated with high morbidity and mortality. We evaluated the health status of readily accessible Manila clam juveniles from Korea that were proposed for importation into Mexican waters where they would increase in size, and then be shipped into the United States, either to market destinations or to receiving waters. The examination of the clams was performed as a preliminary assessment for a producer considering the importation of Korean Manila clams. We report finding a high prevalence of a *Perkinsus* sp. causing significant tissue damage in juvenile Korean Manila clams. Parasite taxonomic verification was made using a genus-*Perkinsus* SSUrRNA gene-specific DNA probe for *in situ* hybridization. The use of this probe is validated and reported for the first time. As a result of this finding, no importation of this clam stock took place. It is urgently important to make widely known the risk of the spread of this disease into the clam stocks of the west coast of North and Central America to prevent such an introduction. In addition, we report new information regarding the prevalence and intensity of this disease in juvenile clams available for export, as well as pathologic features of the disease.

KEY WORDS: *Venerupis (Tapes) philippinarum*, juvenile clam infection, *Perkinsus* sp., DNA probe, *in situ* hybridization

INTRODUCTION

Manila clams (*Venerupis philippinarum*, A. Adams and Reeve 1850) are an important aquaculture species on the west coast of North America. More than 7 million pounds of littleneck clams, predominantly *V. philippinarum*, were produced in Washington, California, and Oregon in 2000 (Pacific Coast Shellfish Growers Association 2003), and additional production occurs in British Columbia, Canada. Although Alaska produces native littleneck clams, *Protothaca staminea* (Conrad 1837), Manila clams are exotic, and importation for aquaculture purposes is prohibited. *Venerupis philippinarum* is also an important aquaculture species in Europe and Asia, and is infected with *Perkinsus* sp. on both continents. Specifically, *Perkinsus atlanticus* occurs in Europe (Navas et al. 1992), a *P. atlanticus*-like parasite occurs in Japan (Hamaguchi et al. 1998), and *Perkinsus* sp. occurs in Korea (Choi & Park 1997) and China (Liang et al. 2001). Consistent with the close homology noted between DNA sequences at several *P. atlanticus* and *Perkinsus olseni* loci by diverse investigators, Murrell et al. (2002) assert these parasitic species to be synonymous, with taxonomic priority to the *P. olseni* name.

In contrast, clams from the west coast of North America are free of *Perkinsus* sp. infections. A survey of Manila clam health and conditions on the west coast of North America (Pacific Shellfish Institute 2001), and the required examination of over 3000 clams for health certifications from 1991 to 2002, showed no evidence of *Perkinsus* sp. infection. Moreover, such infections have not been reported elsewhere on the west coast during routine annual examinations and frequent health examinations of brood stocks and seed clams since 1985. In addition, *Perkinsus* sp. in-

fection has not been reported in the native littleneck clam *P. staminea* or any other bivalve species from the west coasts of North or Central America.

Manila clams may be imported as a live market product from Korea, Japan, or other Asian countries into North America. In 1998, we evaluated the health status of juvenile Manila clams from Korea that had been proposed for importation into Mexican waters, where they would gain size before shipment to the United States, either to market destinations or to receiving waters for further grow out. The examination of clams was performed as a preliminary assessment for a producer considering the importation of Korean Manila clams. We report the finding of a high prevalence of a *Perkinsus* sp. causing significant tissue damage in juvenile Korean Manila clams.

As a result of this finding, no importation of this clam stock took place. It is urgently important to make widely known the risk of the spread of this disease to west coast North American clam stocks to prevent the introduction of this debilitating and lethal clam parasite. In addition, we report here new information regarding the prevalence and intensity of this disease in juvenile clams that are available for export, as well as pathologic features of the disease. Finally, a novel genus-*Perkinsus* DNA probe for *in situ* hybridization (ISH) assays on histologic samples is described.

Taxonomic references to the Manila clam (also commonly referred to as the Japanese littleneck clam) in the scientific literature are particularly confusing. We have designated the species as *V. philippinarum* in accordance with the Committee on Scientific and Vernacular Names of Molluscs within the Council of Systematic Malacologists, American Malacological Union (American Fisheries Society 1998). The common name Manila clam is also found in the literature, apparently in reference to the same species, associated with scientific designations of *Tapes philippinarum*, *Ruditapes philippinarum*, *Tapes semidecussatus*, and *Tapes japonica*.

MATERIALS AND METHODS

A total of 64 Manila clams [16–32 mm shell length (SL)] from Incheon Bay, South Korea, were clinically examined in February 1998 and were fixed whole in Davidson's shellfish fixative (Shaw & Battle 1957). These tissues were processed for routine histologic examination.

A representative tissue section containing parasites was evaluated by ISH. The genus-*Perkinsus* DNA probe was designed to specifically target SSU rRNA sequences of *Perkinsus* species by aligning the available SSU rRNA gene sequences, while not hybridizing to the sequences of closely related parasite taxa including dinoflagellates and apicomplexans. An SSU rRNA gene sequence is not available for *Perkinsus qugwadi*. The resulting probe Perksp700DIG (5'-CGCACAGTTAAGTRCGTGRGCACG-3') was 5' end-labeled with digoxigenin (Sigma-Genosys, The Woodlands, TX). ISH assays were performed as previously described (Stokes & Bureson 1995, Stokes & Bureson 2001), except that 125 µg/mL pronase was used for permeabilization, instead of proteinase K, for a 30-min digestion, and a probe concentration of 7 ng/µl was used for hybridization. The probe was tested on an array of *Perkinsus* sp.-infected, paraffin-embedded tissues (Table 1), including *Perkinsus marinus* in *Crassostrea virginica*, *P. atlanti-*

cus in *Ruditapes decussatus*, *P. olseni* in *Haliois laevigata*, *Perkinsus andrewsi* in *Macoma balthica*, *Perkinsus* sp. in *Vereurupis philippinarum* from Japan, *Perkinsus chesapeakei* in *Mya arenaria*, *Perkinsus mediterraneus* n. sp. in *Ostrea edulis* (Casas et al. in press), *Perkinsus* sp. in *Chama pacificus*, and *P. qugwadi* in *Patinopecten yessoensis*. Probe specificity was validated by testing tissue sections of the blue crab *Callinectes sapidus*, which was infected with the parasitic dinoflagellate *Hematodinium* sp. (Shields 1994), *Hematodinium* sp.-infected Norway lobster *Nephrops norvegicus* (Field & Appleton 1995), *Haplosporidium nelsoni*-infected and *Haplosporidium costale*-infected *C. virginica* oysters, and spot prawn *Pandalus platyceros*, infected by an undescribed haplosporidian-like protozoan parasite (Bower & Meyer 2002). Replicate sections of nonspecific ISH assay signal controls of each sample were tested identically, except that they received hybridization buffer without probe during the overnight hybridization step.

RESULTS

Histologic Evaluation of Infected Clams

The prevalence of juvenile clams infected with the presumptive *Perkinsus* sp., was 59 of 64 (92%), based on histologic examination. The protozoa were systemically distributed in a variety of organs, most typically in subepithelial areas of the gills, and fre-

quently in the mantle and labial palps. Parasites were often associated with tissue hemocytosis (Fig. 1) and occurred as single or multiple trophozoites (Fig. 2). In severe infections, the parasites were more abundantly distributed in the tissues, including the vascular sinuses around the digestive diverticula. Broad areas of the subepithelial connective tissues were composed of solid masses of parasite cysts in the most severe infections. In many cases, the parasites were contained within a thin-walled cyst formed by one to several host cells (Fig. 3). Such encapsulations contained up to 10 protozoan cells and associated hemocytosis. The parasites were often characterized by the presence of an eccentric vacuole (Fig. 1 and 3), characteristic of *Perkinsus* sp. trophozoites.

Confirmation of *Perkinsus* sp. by ISH

The genus-*Perkinsus* SSUrRNA gene probe Perks700DIG demonstrated strong hybridization to *Perkinsus* sp. cells in all of the tissue sections, except those of *P. qugwadi* infecting *P. yessoensis* (Table 1 and Fig. 4A–I). No hybridization to parasite cells of other genera was observed. ISH of parasite cells in tissue sections of infected Korean Manila clams with this genus-*Perkinsus* probe confirmed the genus level affiliation of the parasites in our sample of juvenile Korean Manila clams (Fig. 5).

DISCUSSION

We report the confirmation by ISH assays and histology of *Perkinsus* sp. infections in Manila clam seed proposed for the introduction into Mexican waters and the subsequent transport to growout sites on the Pacific coast of the United States. This is the first confirmation by a molecular diagnostic probe of *Perkinsus* sp. infection of Korean Manila clams. As a result of these findings, the plan for importation of these clams was rejected by the shellfish producer, and no Korean seed clams were imported to the west coasts of Mexico or the United States. However, the ready availability of such infected seed clams from Korean or Japanese producers requires vigilance to ensure that no such importations take place into areas that are free of the pathogen, such as the west coasts of North and Central America. Reports of lethal *Perkinsus* sp. infections in European and eastern Asian Manila clams from latitudes as far north as that of northern Oregon, confirm the high

likelihood that such infections, if introduced, could persist and be transmitted, with damaging results to both wild and cultured clam stocks along the Pacific coasts of North and Central America.

This study demonstrated that infection prevalence in seed clams ranging from 16 to 32 mm SL can be nearly 100% and that high parasite intensities cause significant histologic damage to the organs of infected clams, particularly the gills.

Choi and Park (1997) studied five species of Korean clams for infections by *Perkinsus* sp. using Ray's fluid thioglycollate medium (Ray 1966) and found infected Manila clams along the south coast of Korea. While no infection occurred in clams of <15 mm SL, nearly 100% infection prevalence occurred in clams of >20 mm SL. Park et al. (1999) reported mass mortality of Manila clams along the west and south coasts of Korea over a period of several years, which was associated with *Perkinsus* sp. infections. They reported 100% infection prevalence in 142 clams from Komsoe Bay on the west coast of Korea with moderately severe mean parasite intensities of 2.87 based on the infection intensity scale of Choi et al. (1989). A negative correlation was found between the intensity of *Perkinsus* sp. infections and the clam condition index, while clam size was positively correlated with infection intensity.

Maeno et al. (1999) reported *Perkinsus* sp. parasites in Manila clams from an inner bay of the western part of Japan in April 1998, using genus-*Perkinsus*-specific antibodies. These authors concluded that the parasites were *Perkinsus* sp. based on a positive reaction with both single and clustered trophozoites. Hamaguchi et al. (1998) have reported the first detection of *Perkinsus* sp. in Japanese Manila clams. Anecdotal information that we received from the Korean supplier of the seed clams and their Japanese customers indicated that the Manila clam seed had been transported from the Korean source to Japan for at least 20 y with no unusual mortalities or loss of growth reported. This anecdotal re-

port and the multiple reports of the *Perkinsus* sp. parasite occurring about 1997 or 1998 in Japan and Korea suggest that it could have been a new introduction to the Korean clams, as well as the Japanese clams, at about this time.

Manila clams and other bivalve species from Europe reportedly have been infected with *Perkinsus* sp., as follows: *P. atlanticus* from the Mediterranean coast of Spain (region of the Ebro Delta, Tarragona, Spain) infected *R. philippinarum* (Sagrasta et al. 1996); Manila clams from the Lagoon of Venice in northeast Italy infected with a *Perkinsus* sp. (DaRos et al. 1998); and *P. atlanticus* infected the carpet shell clam (*R. decussatus*) from European locations (Ordas et al. 2000). Villalba et al. (2000) reported a significant correlation between the SL of *R. decussatus* and *P. atlanticus* infection intensity. No clams of <20 mm SL were infected, and the highest seasonal parasite intensities occurred in spring and late summer to early autumn.

The relationship of *Perkinsus* sp. in European waters to the *Perkinsus* sp. found in Korea and Japan is unknown at this time. Nonetheless, this and other studies cited in this report indicate the presence of this damaging parasite in Korean and Japanese Manila clams, confirmed first in this study by histology and then definitively by the *Perkinsus* sp.-specific probe presented for the first time in this article. This knowledge can be used to prevent the unintentional introduction of this parasite to west coast of North and Central America. We urge that the science presented in this article be applied by shellfish growers, and by natural resource and conservation managers to prevent such a damaging introduction.

FILTRATION AND RESPIRATION RATES OF THE ELONGATE SUNSET CLAM *GARI ELONGATA* LAMARCK 1818 UNDER NATURAL LIGHT CONDITIONS

ANNABELLE G. C. DEL NORTE-CAMPOS*

Marine Biology Laboratory, Division of Biological Sciences, College of Arts & Sciences, University of the Philippines in the Visayas, Miagao, Iloilo 5023, Philippines

ABSTRACT This study is a first step in evaluating the potential of the suspension-feeding clam *Gari elongata* as a biofilter in lake/pond polyculture systems. Filtration and respiration rates across all sizes of *G. elongata* were measured in the laboratory under natural light conditions. Filtration rates (F) were determined in a batch system at four concentrations (10 , 25 , 50 , and 100×10^4 cells mL^{-1}) of the phytoflagellate *Isochrysis galbana*. Filtration rates were higher at lower concentrations but decreased with the highest concentration, indicating a possible overloading of the gill sorting mechanism. For the given conditions, mean F at $45.11 \text{ h}^{-1} \text{ g}^{-1}$ was considered optimal at 25×10^4 cells mL^{-1} . This value proves to be the highest F value reported so far, for bivalves. The results further qualify the species as a biofilter in fresh- to brackishwater polyculture setups. F values were further observed to decrease with body weight, although there was a wide variation. The $F:W$ exponent computed for the species was inconsistent with reported trends, which may be due to either light conditions or algal cell size. There was no increase in the species' respiration rate (R) with feeding. For unfed clams, R decreased with size, but there was high variation, and the relationship was not significant. At optimum algal concentration, R per unit body mass for fed clams, decreased with size, and the computed $R:W$ exponent value points to a less rapid increase in size-respiration rate than most other bivalves.

KEY WORDS: filtration rates, respiration rates, *Gari*, body size, algal concentration, physiology

INTRODUCTION

Intensification in aquaculture has become a choice option to ensure food security in the face of an ever-increasing population and parallel demand for fishery products. Hence, there is a continuous effort to increase production in fishponds, pens and cages (Briggs & Funge-Smith 1994, Funge-Smith & Briggs 1998). Along with this effort, however, are emergent concerns relating to the environmental impact of aquaculture, specifically the increased organic loading from excess feeds and wastes, observed in freshwater lakes and coastal habitats.

In the light of these concerns, polyculture with biofilters, or co-rearing invertebrates and aquatic macrophytes with fish and/or crustaceans, may serve as the solution (e.g., Shpigel & Fridman 1990, Shpigel & Blaylock 1991, Shpigel et al. 1993, Ahlgren 1998). These filter- (e.g., bivalves) or deposit- (e.g., sea cucumbers) feeding invertebrates and seaweeds can help maintain water quality by using up excess bottom-accumulated organic matter (e.g., excess feeds, fecal material) and suspended dissolved nutrients, thereby converting these to usable or harvestable biomass.

Although polyculture in marine waters has received ample attention, using bivalves in freshwater systems is a relatively new topic. A possible biofilter species is the filter-feeding psammobiid clam *Gari elongata* Lamarck, a lesser-known bivalve species that burrows in shallow, freshwater to brackish (0–15 ‰) waters in Panay island, located in the west central Philippines (del Norte-Campos, submitted). It is characterized as having brownish black, elongated, and moderately thick shells. This species may be a potential polyculture species in tilapia cage culture (lakes) and/or carp and catfish ponds. It is harvested and sold for food in local markets, albeit at low prices and quantities. Although abundant, the species has received little scientific attention, possibly because they closely resemble the more popular and studied, brown mussel (*Modiolus metcalfei*) in appearance.

This study on *G. elongata* had the overall goal to quantify the components of the species' energy budget, $C = f + U + P + R$ (modified from Windell 1978), where the energy of the food consumed (C) is apportioned to the energy lost in the form of feces (f), urine or excreta (U), and respiration or metabolic cost (R) and gained in the form of tissue growth (P). Food consumption (C) in filter-feeding bivalves is a function of filtration (F) and absorption (A).

The specific objectives of the present work were to measure the 1) filtration rates (F) of the species, in terms of body size and algal concentrations and 2) respiration rates (R) for unfed and fed individuals of various size classes.

MATERIALS AND METHODS

Study Area and Laboratory Experiments

The clams used for this study were collected by hand from rice farm irrigation canals in Barotac Viejo, Iloilo province, eastern Panay Island in west central Philippines (Fig. 1). Water depth in the area was around 1 m, with salinity ranging from 0 to 10 ppt. Bottom substrate was muddy to silty. These canals drain into the Alacaygan River, which empties into the Banate Bay. The clams were brought to the laboratory and acclimated for at least 3 days prior to the start of the experiments. Although the species tolerates salinities of up to 15 ppt (del Norte-Campos, submitted for publication), all experiments were conducted using freshwater, with water temperatures ranging from 26 to 30 °C.

Morphometrics

Shell length (in mm) was measured with the use of a vernier caliper. Filtration and respiration rates were determined for six size classes: 10–19.99, 20–29.99, 30–39.99, 40–49.99, 50–59.99, and 60–69.99 mm. Wet and dry weights (g) of individuals from across all size ranges were taken. Soft tissue was dried at 60 °C to constant weight. The relationship between shell length and dry soft tissue weight was derived through regression analysis. For each size

Figure 1. Site of collection of the clam *Gari elongata*: irrigation canal (approx. 0.5 m in depth) in Barotac Viejo, Hoilo, Panay Island, The Philippines.

class, three trials (replicates) were conducted, with each trial consisting of three individuals.

Microalgae

The phytoflagellate *Isochrysis* aff. *galbana* Tahitian (*T-Iso*), harvested during its logarithmic phase of growth, was used as food. The species was selected for its relatively small size (mean cell diameter approx. 4 μm), and nutritional value, that it is therefore, widely used in mariculture (Taylor et al. 1997, Brown et al. 1999, Phatarpekar et al. 2000).

Filtration Rates

Four microalgal concentration levels were tested: 10, 25, 50, and 100×10^4 cells mL^{-1} . These values correspond to levels that are normally encountered in aquaculture ponds (Duerr et al. 1998). The desired concentration and volume was obtained through dilution.

The volume of water that each bivalve filtered of particulate material (F , L h^{-1} ; or the indirect method of Jørgensen 1990) was determined from separate containers (V approx. 8 L) holding the bivalves. Water sampling was done every thirty minutes during a 3-h experiment. A 5-mL sample was collected each time from the center of the containers and immediately fixed with two drops of Lugol's solution to prevent further reproduction of the algal cells. The density of the algal population in every sample was measured by direct algal cell count using a hemocytometer and a microscope. Three replicate counts were made for each sample. A parallel control set-up showed no significant change in algal cell densities during the 3-h observation period.

For each clam, the filtration rate was determined using the formula $F = Vr$, where r is the rate constant (h^{-1}), or the negative of the slope obtained from regressing $\ln C$ or cell concentration (mL) against time (h) and V is volume of the diluted algal suspen-

sion containing the clams. Because filtration rates were measured in a batch system where algal concentrations do not remain constant, only the descending limb of the curve was included in the determination of the slope, that is, the flatter portion (asymptote) was excluded. Derived filtration rates were compared for the four algal cell concentrations, and based on this, an optimal cell concentration was chosen. For the optimum concentration, the relationship between F and dry wt (g) was derived, and compared with reported values. To show the relationship of filtration rates with size, filtration rates were expressed in terms of the dry weight of the organisms ($\text{L h}^{-1} \text{g}^{-1}$) and plotted against the corresponding dry weights (g) of the organisms.

Respiration Rates

Respiration rates were measured for both unfed (ration = 0; starved for 24 h) and fed clams. The latter were also given *T-Iso* at the observed optimal algal concentration in a holding container for at least 15 min. prior to respiration measurements. For both unfed and fed clams, three individuals per size class were placed in a sealed transparent Plexiglas chamber (15 \times 15 \times 15 cm, or 3.4-L capacity). Oxygen concentration in each chamber was measured at 30-s intervals using a YSI DO meter. A parallel control with no clams was run to test the stability of the chamber. Respiration rate (R , $\text{mL O}_2 \text{ ind.}^{-1} \text{ h}^{-1}$) was determined as the negative of the slope of $\ln \text{O}_2$ concentration vs. time (h). Initial data plots served as bases to decide the time series portion that was included. The relationship between R and dry wt was likewise derived, and compared with reported values in the literature. To show the effect of size as in above, respiration rates were also expressed in terms of the dry weight of the organisms ($\text{mL O}_2 \text{ h}^{-1} \text{g}^{-1}$) and plotted against the dry weights (g) of the organisms.

RESULTS

The range of sizes used in the experiments was 11.8–67.9 mm, corresponding to 0.008–1.298 g dry weight. Filtration rates (F) for the algal concentrations of 10, 25, and 50×10^4 cells mL^{-1} averaged for all sizes were found to be higher (81.3, 45.1, and $68.5 \text{ L h}^{-1} \text{g}^{-1}$ resp.) and lowest ($25.9 \text{ L h}^{-1} \text{g}^{-1}$) at the highest algal concentration of 100×10^4 cells mL^{-1} (Fig. 2). Although the differences were found to be statistically significant, the optimum algal cell concentration selected was 25×10^4 cells mL^{-1} , as this was the median of the range of concentrations where F values were higher. This would further be the logical choice considering that among all four concentrations, it was with this concentration that the F was

Figure 2. Filtration rate ($\text{L h}^{-1} \text{g}^{-1}$) of *G. elongata* versus shell length (mm) under different algal concentrations (10, 25, 50, and 100×10^4 cells mL^{-1}). Values from the 10-mm size class are $\times 10^{-1}$.

highest for four size categories (20, 30, 40, and 50 mm) out of the six (excluding 10- and 60-mm size classes; Fig. 2).

Filtration rates ($l\ h^{-1}\ g^{-1}$) plotted against dry weight (g) was shown to decrease with size with the slope equivalent to -1.1196 and $r^2 = 0.9723$ (Fig. 3). The regression was found to be significant ($P < 0.01$), i.e. the intercept and slope are significantly different from 0.

Respiration rates in terms of weight ($ml\ O_2\ h^{-1}\ g^{-1}$) plotted for both unfed (Fig. 4) and fed (Fig. 5) clams were observed to decrease with size. The relationship for the latter was significant, with a slope of -0.6712 and $r^2 = 0.848$. The mean computed rate for unfed clams were $0.61\ ml\ O_2\ ind^{-1}\ h^{-1}$, whereas at optimal algal concentration values ranged from 0.11 to $0.96\ ml\ O_2\ ind^{-1}\ h^{-1}$.

DISCUSSION

The observed initial increase and subsequent decrease in filtration rates of *G. elongata* with increasing cell concentration (Fig. 2), is similar to several results on different lamellibranch bivalves (e.g., Winter 1970, Tenore & Dunstan 1973, Schulte 1975, Gerder 1983) indicating that filter feeding is affected by cell concentration. This has likewise been observed even for bivalve larval stages. In the oyster *Ostrea edulis* for example, ingested ration was correlated with algal cell concentration, whereby further increases in the latter failed to support higher ingestion rates and faster growth rates (Beiras & Perez Camacho 1994). It is apparent therefore, that bivalves regulate the amount of water filtered in relation to food concentration. The increase in filtration rates would suggest sub optimal algal concentrations, whereas inhibition of filtering activity would indicate a possible overloading of the gill sorting mechanism at higher cell concentrations (50 to 100×10^4 cells ml^{-1} ; Winter 1978). This adjustment behavior, which could possibly be linked to satiety, was further observed to be coupled with mucus secretion and pseudofeces production at high cell concentrations, meaning that the digestive capacity of the clams has been exceeded (Riisgård & Mohlenberg 1979).

The filtration rates measured for this species proved to be the highest of values reported for bivalves (Table 1). As shown in Table 1, literature values for tropical and subtropical species measured for a variety of conditions, range from 1.9 to $11.5\ l\ h^{-1}\ g^{-1}$, with the highest values reported for pearl oysters *Pinctada margaritifera* and *P. maxima* (Yukihira et al. 1998). The filtration rates of temperate bivalves on the other hand, were reported to range from 0.6 to 14.7 , with the highest values reported likewise for the pearl oyster *P. fucata martensii* (Numaguchi 1994). The present values refer however, to smaller clams, compared with the bigger sizes of pearl oysters (36 – 185 mm) used by Yukihira et al. (1998).

Figure 3. Filtration rate ($l\ h^{-1}\ g^{-1}$) of *G. Elongata* versus dry weight (g), $F = 2.0853\ DW^{-1.1196}$; $r^2 = 0.9723$, $n = 18$, X-axis in log scale.

Figure 4. Respiration rate ($ml\ O_2\ h^{-1}\ g^{-1}$) of *G. elongata* versus dry weight (g) for unfed individuals ($R = 0.5062\ DW^{-1.1544}$; $r^2 = 0.955$, $n = 21$). X-axis in log scale.

Thus, the higher filtration rates of smaller sizes explain the higher mean filtration rates.

Aside from size, the morphology and habit of the species are likewise factors to consider in comparing filtering capacities. According to Yukihira et al. (1998), to maximize growth in pearl oysters, strong and fast water currents is a requisite, especially because they occur in oligotrophic waters. Filtration rates of *G. elongata* are higher compared with those reported for giant clams (0.1 to $3.7\ l\ h^{-1}$, with lowest values measured for *Tridacna derasa* and *T. devoraa*; Klumpp & Lucas 1994). Giant clams, however, are both auto- and heterotrophic, and that despite these lower rates, they achieve large sizes by supplementing suspension feeding by translocation of photosynthates from symbiotic zooxanthellae (Lucas 1994). The high filtration rates of *G. elongata* show that the species is well adapted to its environment, characterized by fast-flowing water currents. A mean growth rate of 0.13 ± 0.06 mm day^{-1} was estimated over a period of 1 year (del Norte-Campos, submitted). Thus for this species, filtering at higher rates could well support high growth rates typical of tropical short-lived species. Furthermore, this ability to filter at higher rates also qualifies it as a biofilter species in fresh- to brackishwater polyculture setups.

In relation, the clearance rates measured for phytoplankton taxa and cyanobacteria filaments in the likewise freshwater (lake) bivalve *Dreissena polymorpha* were in contrast, reported to be lower, ranging from 0.2 to $0.34\ l\ h^{-1}$ (Horgan & Mills 1997). The latter may thus be possibly due to the species' adaptation to a habitat with lesser turbulence.

Furthermore, Jørgensen (1990, 1996) concluded that the capacity of water processing in bivalves is evolutionarily adapted to the

Figure 5. Respiration rate ($ml\ O_2\ h^{-1}\ g^{-1}$) of *G. elongata* versus dry weight (g) for unfed individuals ($R = 0.4620\ DW^{-0.6712}$; $r^2 = 0.848$, $n = 18$). X-axis in log scale.

concentrations of suspended food, primarily phytoplankton. Initial experiments showed that *G. elongata* had higher filtration rates under dark feeding conditions (Piñosa, unpublished observations), and this could perhaps be explained by the natural water conditions (silty) in the clam's biotope. Difference in day and night feeding was similarly observed in the zebra mussel *D. polymorpha* inhabiting freshwater lakes (Horgan & Mills 1997).

The decrease in filtration rate per unit body mass with increase in size (Fig. 3) is consistent with reported trends (e.g., Widdows 1978). However, the computed *F:W* exponent value (2.0753) does not fall within the range (0.3 to 0.8, mean = 0.62) reported for several filter-feeding bivalves (Bayne & Newell 1983). This may be attributed to the wide variability in the results. However at the same time, there are also reports regarding the absence of relationship between filtering activity and sizes (e.g., Horgan & Mills 1997). The present results may likewise, be due to less preferred light conditions used in the experiments. Preliminary work on the species' filtration rates also suggested that the highest preference was for the smallest algal size, that is, *Nannochloropsis* sp. (Piñosa, unpublished observations). It may be possible then, that the cell diameter of *T-Iso* is still somewhat large for *G. elongata*.

Reported respiration rate values (Table 1) range from 0.3 to 1.05 $ml\ O_2\ h^{-1}g^{-1}$ in tropical and subtropical bivalves, 0.1 to 1.06 $ml\ O_2\ h^{-1}g^{-1}$ for giant clams, and 0.06 to 0.93 $ml\ O_2\ h^{-1}g^{-1}$ for temperate bivalves. Thus, the values for *G. elongata* of 0.11–0.96 $ml\ O_2\ h^{-1}$ fall within the reported range. Bayne & Newell (1983) gave about 0.7 (range 0.4 to 1.0) as the mean value of allometric exponents for the *R:W* relationship for a variety of marine mollusks. Thus the value (0.4620; Fig. 5) for fed *G. elongata* from this study fall in the lower range, which means that there is less rapid increase in the size-specific metabolic rate of this species than most other bivalves.

The study showed that the species is suitable for use as a biofilter organism. This could further be verified by conducting experiments in polyculture set-ups, both under laboratory and field conditions.

ACKNOWLEDGMENTS

This study received financial support from the University of the Philippines (UP) System-Creative and Research Scholarship Pro-

gram (CRSP). M.A. Tad-y provided laboratory assistance. W. L. Campos gave suggestions and help in the preparation of the manuscript. Laboratory space was kindly provided by the UPV-Institute

of Aquaculture Hatchery, kindly facilitated by S.S. Garibay. The author thanks the reviewers for their helpful suggestions and comments.

EL NIÑO AND LA NIÑA EFFECTS ON REPRODUCTIVE CYCLE OF THE PEARL OYSTER *PINCTADA MAZATLANICA* (HANLEY, 1856) (Pteriidae) AT ISLA ESPIRITU SANTO IN THE GULF OF CALIFORNIA

J. ANGEL GARCIA-CUELLAR,^{1,2,*} FEDERICO GARCIA-DOMINGUEZ,¹

ABSTRACT The impact of El Niño (1997–1998) and La Niña (1998–1999) on the reproductive cycle of the pearl oyster *Pinctada mazatlanica* was studied by histologic observation of gonads, determination of the conditioning index, and oocyte monthly mean diameter, which are related to sea surface temperature and availability of food. Available food was determined by comparison between seasonal and a standard concentration of chlorophyll *a*. Oyster specimens were collected from Isla Espiritu Santo in the Gulf of California from May 1997 to November 1999. A direct relationship of spawning to temperature was observed from July to October. Concentrations of chlorophyll *a* were related to the stage of gonad development. The reproductive process was related to the conditioned index. Reproductive activity during El Niño was longer, with spawning in July to November 1997 and July to October 1998, and more intensive (in terms of population spawning frequency) than that during the La Niña event, when the spawning occurred during August to November 1999.

KEY WORDS: El Niño, La Niña, pearl oyster, *Pinctada mazatlanica*, reproduction

INTRODUCTION

The pearl oyster *Pinctada mazatlanica* is distributed from the west coast of the Baja California Peninsula south to Peru, including the southern part of the Gulf of California and islands around the Peninsula (Keen 1971, Martínez 1983). During the past century, the quality of the pearls produced by this species supported an important pearl fishery in the Gulf of California, which was the incentive for colonization of Baja California Sur (Cariño & Caceres-Martinez 1990, Monteforte & Cariño 1992). The fishery was closed by the Mexican government in 1938 because of overfishing (Keen 1971, Monteforte 1990, Sevilla 1969).

The pearl oyster *P. mazatlanica* is considered a potential and feasible resource to be developed by mariculture (Monteforte 1990). Thus, its reproductive biology is a relevant study subject. In Mexico, some studies have been performed on cultured specimens (Diaz 1972, Garcia-Gasca 1992, Gaytan et al. 1993, Saucedo-Lastra & Monteforte 1997) and on wild populations (Monteforte 1991, Moreno & Moreno 1994, Wriqth 1997). Studies of reproduction in wild populations from Bahía de La Paz were performed by Sevilla (1969) and Garcia-Dominguez et al. (1996); from Guaymas, Sonora, by Arizmendi-Castillo (1996); and from the Golfo de Nicoya, Costa Rica, by Solano-Lopez et al. (1997). In these works, there were no reported relationships and effects on reproduction in *P. mazatlanica* by El Niño and La Niña events. This study describes the effects on the reproductive cycle of *P. mazatlanica* through changes in sea surface temperature and availability of food due to the El Niño and La Niña climatic events.

MATERIALS AND METHODS

Specimens were collected monthly and randomly from May 1997 to November 1999 (except January 1999) in a wild population located near Isla Espiritu Santo, B.C.S. (Fig. 1), from a depth of 4 to 6 m by personnel using scuba gear. A total of 523 organisms were collected, ranging from 20.4 to 228.3 mm shell length

(mean, 119.7; SD, 27.6) and 21.2 to 167 mm shell height (mean, 113.9; SD, 23). Before dissection, the shell length and height were measured with calipers (0.01 mm resolution); subsequently, the wet weight was obtained by electronic scales (0.01 g resolution). The visceral mass (including the gonad) was fixed in a solution of 10% formalin prepared with seawater, dehydrated in an alcohol series dilution, and embedded in paraffin (Luna 1968). Sections, in a frontal and dorsal plane, 5- to 6- μ m thick, were made and stained with Harris' hematoxylin and eosin (Luna 1968).

The diameter of at least 100 oocytes was measured using digitalized images from the histologic preparations (Sigma Scan Pro-4 software program), in each of seven females per month selected randomly. The measurements were made along the longest axis in the oocytes sectioned through the nucleus containing clearly visible nucleoli. From this data, mean size and standard deviation were obtained. The specimens with few measurable oocytes and extensive phagocytosis were not considered, following the criteria of Grant and Tyler (1983a, 1983b).

Sex was determined by microscopic analysis, and the percentage of each sex was obtained. The sex ratio was determined and examined for deviation from the expected ratio of 1:1 by chi-square (χ^2) analyses. Condition index (CI), using the formula proposed by Ricker (quoted by Bolger & Connolly 1989), was selected because it takes into account those cases in which growth is not isometric, as occurs in *P. mazatlanica*, and could describe in the best way the general condition variations and their relationship with the reproductive event:

$$CI = PH/L^b \times 1000$$

where CI was determined by dividing the visceral mass wet weight (PH) by the anteroposterior length (mm) and powered by b (value from the slope, which resulted from the power correlation from both variables). We obtained CI means for each monthly sampling.

Sea surface temperature (SST) values were obtained by Coastal Zone Color Scanner (CZCS) from NOAA and chlorophyll *a* concentrations from the SeaWiFS Project, NASA/Goddard Space Flight Center and ORBIMAGE. Anomalies were estimated as de-

partures from the averaged monthly cycle; on this basis, we defined the periods influenced by El Niño (May 1997 to October 1998, positive anomalies) and by La Niña (November 1998 to November 1999, negative anomalies).

The condition of the gonad was determined by microscopic

analysis. Each specimen was assigned a specific stage of gametogenic development. Stages were assigned on the basis of the classification described for *P. mazatlanica* by Sevilla (1969) and Garcia-Dominguez et al. (1996). This classification divides the gametogenic cycle into five stages: indifferentiated, developing, ripe, partially spawned, and spent. The relative frequency of each gonad phase was determined. The reproductive period was considered at spawning stage.

RESULTS

Gonad Developmental Stages

The microscopic anatomy from each gonad stage of *P. mazatlanica* did not differ from those described by Sevilla (1969), Garcia-Dominguez et al. (1996), and Saucedo-Lastra and Monteforte (1997).

Reproductive Cycle

The reproductive cycle is shown in Figure 2. We observed that during the El Niño, spawning occurred from July to November 1997 and July to October 1998 (maximum peaks in July to September 1997, and July and August 1998). This period was characterized by the constant appearance of gametogenic activity in developed and ripe stages and relatively poor inactive (indifferentiated stage). The population spawning frequency was 69% mean and 90% maximum. During the La Niña, spawning took place from August to October 1999 (maximum peaks on August to October), predominated by the developed stage and more presence of the inactive stage. The population spawning frequency was 45.6%

Figure 2. Relative frequency of gonadal stages of *P. mazatlanica* from May 1997 to November 1999 at Isla Espiritu Santo, Gulf of California.

mean and 70% maximum. In both periods, the spawn occurred between 27 and 30 C and was suspended at temperatures under 25 C.

Sex Ratio

Out of 523 specimens sampled, 250 (47.8%) were males, 205 (39.2%) were females, 12 (2.3%) were hermaphroditic, and 56 (10.8%) were undifferentiated. The sex ratio (1.22 male:1 female) did not differ significantly ($P < 0.05$, $n = 455$) from an expected 1:1 ratio.

Analysis of Oocyte Size

Mean oocyte diameters are shown in Figure 3. Maxims were observed during May and June 1997, June 1998, and July 1999. From September to December 1998 and February to March 1999, there were specimens with few or no measurable oocytes. The highest mean oocyte diameter values during El Niño corresponded to the ripe stage (May to June 1997, and April to May 1998), and the lowest mean values corresponded to the spent stage (September to November 1997 and August to October 1998). This relationship did not occur during La Niña.

Condition Index

To validate the CI determination, the height and visceral weight variables were compared. Using a power correlation, we obtained a value of $r = 0.88$ and slope $b = 2.77$ ($P < 0.05$, $n = 523$). The CI values fluctuated between 8–16% and were related to the species reproductive stages, maximum values coinciding with the de-

velopment stage, and the minimum values with the spawn stage (Fig. 4).

Temperature and Anomalies

During the study, the SST varied from 19 to 30.8 C. During El Niño, SSTs varied from 21.6 to 30.8 C, with a maximum anomaly of +2.82 C (January 1998), and during La Niña, from 19 to 28.2 C, with a maximum anomaly of -1.36 C (February 1999). The SSTs and anomalies are recorded in Figure 5.

The relationship between the SST and the relative frequency of spawning are shown in Figure 6. Spawning occurred between the 27 to 30°C interval and was suspended when colder than 25 C. During the El Niño, the highest percentage of population spawned coincided with the highest temperature recordings in August 1997 and August 1998; during La Niña spawning occurred in August 1999, while the highest temperature recorded was during September of 1999.

Photosynthetic Pigment Concentration

Chlorophyll *a* concentrations varied during El Niño from 0.096 to 1.2 mg/m³ and during La Niña from 0.28 to 3.6 mg/m³. In both periods, pigment concentrations were inversely related to the temperature, with the highest concentrations during the winter seasons and the lowest during the spring-summer seasons.

Figure 7 shows the relationship of the reproductive cycle to the pigment concentrations. The highest pigment concentration values were significantly related with the development stage (untransformed data) ($r = 0.75$, $P < 0.05$, $n = 30$) and minimum pigment concentrations values with ripe and spawn stages.

DISCUSSION

The description of gonadic cycle stages and their corresponding microscopic anatomy did not differ from those performed for *P. mazatlanica* by diverse authors (García-Domínguez et al. 1996, Saucedo-Lastra & Monteforte 1997, Sevilla 1969).

There were differences related to the gonadic cycle among El Niño and La Niña events. During El Niño, the developing and ripe stages were constants and in equilibrium along the study period whereas the spawning stage was continuous and longer on time duration and more intensive (related to population spawning frequency): the indifferentiated stage was present in low frequency. In contrast, during La Niña the developed stage was predominant along the study period with intermittent and short ripe stage and the reproductive stage was of minor duration and intensity.

Studies performed on *P. mazatlanica* reproduction (García-Domínguez et al. 1996) at Isla Espíritu Santo revealed spawn occurrence during June, July, and October 1992 and April 1993, with 30% mean and 33.3% maximum population spawning frequency whereas Sevilla (1969) in Bahía de La Paz found maximum spawning peaks in August and September 1963, with 30.5% mean and 50% maximum population spawning frequency. On cultured population from Bahía de La Paz, Saucedo-Lastra and Monteforte (1997) found only one maximum spawning peak during September 1992 and 30% maximum population spawning frequency. In Guaymas, Sonora, Mexico, *P. mazatlanica* was reported with a maximum spawning peak in June 1994 and 67% maximum population spawning frequency (Arizmendi-Castillo 1996), and from the Golfo de Nicoya, Costa Rica, two maximum spawning peaks in October 1993 and June 1994, with 31.5% mean population spawning frequency were reported (Solano-López et al. 1997). The differences pointed out by the results in the current study proved that in both climatic events, there was real impact on the reproductive stages, suggesting that in the El Niño event, the environmental conditions were most favorable and that this caused intervals among the reproductive stage to be shortened and the gonads to recuperate rapidly, accelerating the ripe stage. Similar results were found by Arntz et al. (1988) and Wolf (1988) during El Niño 1982–1983, in *Argopecten purpuratus* (Pectinidae) at the Peruvian coast, where they observed especially high intensity on spawn.

The sex ratio in both periods did not differ from the expected 1M:1F ratio—this result coincides with those of Saucedo-Lastra and Monteforte (1997) and Solano-López et al. (1997), 1M:0.38F and 1.6M:1F ratios, respectively—but differs from those reported by García-Domínguez et al. (1996) where the females predominated (1.33F:1M). The hermaphroditic frequency in the current study was higher than those reported by García-Domínguez et al. (1996) and Saucedo-Lastra and Monteforte (1997), 0.64% and 0.6%, respectively. In both periods, the highest hermaphroditic frequency was present during the main season of reproductive activity, while males predominated, coinciding with Sevilla (1969) and Saucedo-Lastra and Monteforte (1997) in *P. mazatlanica* and by Behzadi et al. (1997) in *P. fucata*. The results in the current study and others obtained by several authors confirm the protandric condition of *P. mazatlanica* (García-Domínguez et al. 1996, Saucedo-Lastra & Monteforte 1997, Sevilla 1969), as occurs in other *Pinctada* species (Behzadi et al. 1997 and Tranter 1959 in *P. fucata*; Tranter 1958a in *P. albina*; Tranter 1958b in *P. margaritifera*; and Rose et al. 1990 in *P. maxima*).

During the El Niño, the occurrence of highest mean values of oocyte diameter corresponding to ripe stage and the lowest mean values corresponding to the spawn and spent stages allow us to infer that greater oocyte size were liberated to the external environment. This relationship between oocyte diameter and gonadal stages of *P. mazatlanica* reflects the gametogenic cycle, as clearly occurs in other bivalve species studied in normal environmental conditions: *Glycymeris gigantea* (Villalejo-Fuerte et al. 1995), *Spodilyus leucacanthus* (Villalejo-Fuerte & García-Domínguez 1998), and *Periglypta multicostata* (García-Domínguez et al. 1998). This relationship did not occur in the La Niña event.

The maximum and minimum CI values and their fluctuation tendency, in both periods, were similar. This relationship between CIs to the reproductive process suggests a strong influence of the gonad weight over the general organism condition, as was reported for *P. mazatlanica* by Solano-López et al. (1997) in the Gulf of Nicoya, Costa Rica, and also reported for another bivalve species by Ochoa-Baez (1985) for *Modiolus capax* and by Villalejo-Fuerte and Ceballos-Vázquez (1996) for *Argopecten circularis*. These CI fluctuations are associated with the nutritional and reproductive condition of mollusks (Searcy-Bernal 1984), and for this reason we can consider CI a general condition indicator to the specimens that conform *P. mazatlanica* reproductive population and also as the general reproductive process.

The *P. mazatlanica* reproductive cycle showed a seasonable relation to SST. The minimum gonadic activity (indifferent stage) occurred during autumn at El Niño and in winter at La Niña; the highest developing frequency during summer at El Niño and in winter at La Niña; and the ripe stage in the close of spring at El Niño and in middle summer at La Niña. In both periods, when the temperature reached 27°C (middle summer at El Niño, close of summer at La Niña), spawning began and was maintained during all the time (months) while the temperatures were about 30°C (late autumn during El Niño and early autumn during La Niña), and spawning in both periods was suspended at temperatures under 25°C. This crucial interval could be considered as optimum for *P. mazatlanica* spawning and is similar to those reported in the same species by Sevilla (1969), Tripp-Quezada (1991), Arizmendi-Castillo (1996), García-Domínguez et al. (1996), and Saucedo-Lastra and Monteforte (1997). The difference in both periods was that the reproductive event in El Niño was longer in time and more intensive on population spawning frequency, and all this explained was happened to *P. mazatlanica* by García-Domínguez et al. (1996) on "El Niño" 1991–1992, at Isla Espíritu Santo, B.C.S., Mexico, where spawning activity occurred throughout the study period (June 1992 to August 1993). In La Niña, the spawning activity was shorter in time length and began until the 27°C temperature was reached (August 1999). For both periods, temperature was inversely related to CI, and CI was closely related to condition of specimens and they, on lowest temperature periods (winter season), were in indifferent and developing stages having the highest condition values. During the highest temperature periods (summer season), spawning was present and hence the minus CI values.

The oocyte mean diameter during El Niño was related to the ripe and spawning stage and CI, all of them influenced by temperature variations, as pointed out above. During La Niña, this relationship did not occur at all.

Pigment concentration in both periods presented similar sea-

Figure 6. Relationship between the sea surface temperature and the relative frequency of the part-spawning stage from May 1997 to November 1999 at Isla Espiritu Santo, Gulf of California.

sonal fluctuations. The difference between both periods was that during El Niño, the mean, maximum, and minimum pigment concentrations were smaller than those during La Niña. In *P. mazatlanica*, for both periods, gametogenic production (developing

stage) started during winter, coinciding with highest photosynthetic pigment concentration. During ripe and spawning stages, no relationship was found in both periods with pigment concentration, and we assume that these events were realized at the expense of

Figure 7. Relationship between the photosynthetic pigment concentration and the relative frequency of the developing stage from May 1997 to November 1999 at Isla Espiritu Santo, Gulf of California.

organism nutrient reserves. There are observations in many bivalves that gametogenic process takes place at the expense of conjunctive reserve tissue (Galtsoff 1964, Mathieu and Lubet 1993), as the case in the mussel *Perumytilus purpuratus* (Lozada and Reyes 1981) during spawning and in *P. mazatlanica* (García-Gasca 1992) during gamete formation.

During El Niño, pigment concentration was related to CI, but not during La Niña, in this case the fluctuations of CI could be attributed to the irregular gonadic process, as occurred during the developing and ripe stages presented by the specimens during this period. The monthly mean oocyte diameter, in both periods, was not related to pigment concentration, as the maximum monthly mean diameters occurred in summer.

Finally, it may be concluded that temperature was the main factor regulating the spawning time during the El Niño and the La

Niña, and that food availability was not related to the pearl oyster spawning.

ACKNOWLEDGMENTS

This study was conducted as part of an Institutional Program of the Centro Interdisciplinario de Ciencias Marinas (CICIMAR-IPN, Mexico), which is funded by Consejo Nacional de Ciencia y Tecnología (CONACYT-Mexico) and Consejo Nacional de Educación Tecnológica (COSNET-México). Our gratitude to Manuel Zamarrón and Ciro Arista for their help in collecting samples, Fidel Camacho and Jorge Lopez for their work on histologic processing, and the CIBNOR editorial staff for review of the English text. Daniel Lluch-Belda and Federico García-Domínguez received a grant from the Comisión de Operación y Fomento de Actividades Académicas of the Instituto Politécnico Nacional.

RESPONSE PROFILE OF THE CALAFIA PEARL OYSTER, *PINCTADA MAZATLANICA* (HANLEY, 1856), TO VARIOUS SEDATIVE THERAPIES RELATED TO SURGERY FOR ROUND PEARL INDUCTION

MARIO MONTEFORTE,* HORACIO BERVERA AND PEDRO SAUCEDO

Centro de Investigaciones Biológicas del Noroeste, S.C. (CIBNOR), La Paz,

Baja California Sur, CP 23090, México

ABSTRACT Anesthetic drugs are common in management sequences of commercial aquaculture that imply relaxation of specimens. Studies on physiologic response and relationships with functions of body parts are particularly centered in fishes to improve transport, handling, or surgery (i.e., spawning stimulation, sampling of blood and fluids). In pearl oysters, relaxation therapies are important to induce round pearl formation with nucleus-mantle insertions, but the physiologic effect of drugs are poorly known. In the current work, respiration rate (Rr, in $\mu\text{L L}^{-1} \text{g}^{-1} \text{min}^{-1}$) was used as index to establish recovery profiles in *Pinctada mazatlanica* and evaluate relaxation therapies of three doses and two exposure times using propylene phenoxetol (PP), MS-222 (MS), and quinaldine (QN), in comparison with an untreated (CTRL) model. Recovery profiles were explored with median Box-Whiskers plots. Intercept position, dispersion pattern, and range values of Rr, and slope attributes, were inferred through correlation and regression methods. Relationships among these elements were analyzed with three-way ANOVA (time \times dose \times exposure time); recovery profiles were compared within and between drugs through multiple covariance and cluster analysis to explain physiologic responses. Two-way ANOVA at start and end of each trial provided further elements for therapy evaluation. Specimens responded dynamically in this experiment, sharing an overall background variation of Rr strongly influenced by time but with wide differences of significance P level, between 10^{-18} in CTRL and 10^{-10} to $<10^{-24}$ between drugs. CTRL, MS, and PP had negative correlation of Rr over time, whereas it was positive for QN. The influence of dose had grouped P levels between 10^{-11} to 10^{-15} ; exposure time and interactions with dose shared P levels of similar significance between 10^{-3} to 10^{-5} . In comparison with the CTRL model, the use of drugs apparently contributed to decreased stress response in treated specimens, and this was particularly notable in early recovery phases. Variations in dose and exposure time defined specific recovery profiles within drugs. An adequate presurgery therapy should sustain low intercept, low dispersion and range value of Rr, and horizontal slope. QN at doses of 45 mL and PP at 5 mL propiciated low-activity profile during recovery.

KEY WORDS: MS-222, *Pinctada mazatlanica*, propylene phenoxetol, quinaldine, relaxation therapy

INTRODUCTION

Surgery techniques for round pearl formation in pearl oysters have been examined since the early 1940s in publications, reports, manuals, congresses, reunions, and training courses (Gervis 1992, Fassler 1994, SPC-POIB). Videotapes, photography, and the World Wide Web have also become important sources of information. The general agreement recognizes that a pearl culture technician may qualify as "trained" after thousands of essays; even then, differences of success rate (nucleus retention, survival, number and quality of pearls) are notable among technicians and species (Alagarwami 1987, Shirai 1994, Monteforte 1996, Haws 1998, Haws et al. 1999, Nava et al. 2000). Many inherent factors have their own influence, such as the biologic state and health of pearl oysters, response profile to presurgical and healing therapies, quality and profilaxis of workspace, and so forth. Field culture management and environmental conditions also play an important role. Pearl culture technicians coincide in two major requirements that specimens should fulfill before the surgery: (1) newly spawned gonads, empty but prominent enough for assuring nucleus and mantle piece insertion, and (2) adequate relaxation, valves can be easily gapped and body contraction will be slow during the intervention. Thermal shocks and other strategies are applied for spawning induction; anesthetic compounds are commonly used as relaxation treatments (Alagarwami 1987, Ehteshami 1993, Monteforte et al. 1994, Mills et al. 1997, Norton et al. 2000). We investigated the recovery profiles of the Calafia pearl oyster, *Pinctada mazatlanica* (Hanley, 1856), treated with

propylene phenoxetol, MS-222, and quinaldine in different doses and exposure times. *P. mazatlanica* needs adequate presurgery therapies for round pearl stimulation because specimens react defensively if certain level of relaxation is not reached. On the other hand, norms for evaluation of response profiles in mollusks under anesthetics, including pearl oysters (Norton et al. 2000), have been related mainly with behavior (reply level of body parts as a result of mechanical stimulations, time for specimens to attain visible signs of "normal" state, and results in nucleus-mantle retention, survival after cases of expulsion, and total failures). We used the respiration rate as index to describe recovery profiles of the presurgery therapies tested in this study.

MATERIALS AND METHODS

Selection of Therapies

Previous essays with menthol and benzocaine gave deficient results in presurgery sedation of *P. mazatlanica*. Propylene phenoxetol was tested in *P. maxima* (Mills et al. 1997) and *P. margaritifera* (Norton et al. 2000). Both species had suitable relaxation with 2.5 to 5 mL L⁻¹ at exposures of 15 to 20 min, but total failures in round pearl induction in *P. margaritifera* were associated with this drug (Norton et al. 2000). Heasman et al. (1995) found no apparent effect in *Pecten fumatus* at doses of 0.6 mL L⁻¹. In *P. radiata*, Ehteshami (1993) obtained good results with 1 mg L⁻¹ of MS-222. The effect of this substance has been investigated in a wide range of doses and exposure times for several species of fishes and mollusks (i.e., *Oncorhynchus mykiss* by Wagner et al. 2002; *Ostrea edulis* by Culloty & Mulcahy 1992; *Haliois iris* by Aquilina and Roberts 2000; *Elliptio complanata* by Lellis & Plerhoples 1997; and Lellis et al. 2000). Heasman et al.

*Corresponding author. Fax: (+612) 125-3625; E-mail: montefor04@cibnor.mx

(1995) reported hyperactivity and hiperextension of tentacles in *Pecten fumatus* when exposed to 0.1 g L⁻¹ of MS-222. Quinaldine is commonly used in fish transport and broodstock handling; as in the previous drugs, there are different exposure times or doses reported as efficient, depending on the species and type of studies (i.e., *Sparus aurata*, Kumlu & Yanar, 1999; Masee et al. 1995 in larvae of *Sciaenops ocellatus* and *Carassius auratus*). Studies on the effect of quinaldine in mollusks are rare. Heasman et al. (1995) observed valve closure in *Pecten fumatus* when exposed to this substance. Apparently, there is no information regarding pearl oysters.

Experimental Design and Data Treatment

Approximately 3300 cultivated *P. mazatlanica* (wild spat collection) 14 to 16 mo old, were selected for this experiment in September 2001. We confirmed 39/45 specimens in rest or post-spawning stage as expected in the end of reproduction season (Saucedo & Monteforte 1997). A total of 342 were size-selected and divided in three groups of 108 individuals corresponding to each drug: propylene phenoxetol (PP), MS-222 (MS), and quinaldine (QN), plus 18 as controls (CTRL). CTRL monitoring was made in the first place to establish the "standard" profile, then PP, MS, and QN. In each session, pearl oysters were cleaned, measured for shell height (mean = 108.8 ± 6.7 mm SD), and left in starvation for 24 h in a 1500 L tank with filter-aerated seawater stable at 24 ± 1.5°C SD throughout the experiments, which is optimal for the species (Saucedo et al. 2003). With exception of CTRL, trials of 18 individuals were exposed to 3 different doses for each drug during 30 and 60 min into 20 L containers filled with filtered seawater (Table 1). These variables were deduced from the therapies previously outlined. When concluded, a particular exposure time, wet weight (mean = 161.2 ± 33.1 g SD) was measured after placing pearl oysters in ventral position and open for few seconds to drip water excess. Along with 9 untreated individuals per "exposure" time, they were transferred into respective respiration chambers already stabilized on oxygen concentration (Saucedo et al. 2003). Three YSI-58 oxygen-meters provided records every 10 or 20 min (Table 1), ending when the variation between subsequent measurements trended to stabilize and/or to appear alike CTRL. Calibration of YSI meters was checked at start and end of each experimental session in comparison with blank

respirations chambers (1 per session). Normality for shell height was confirmed with a K-S test ($d = 0.10, P > 0.2$). Wet weight had differences, but the significance level was conservative ($d = 0.15, *P < 0.05$). Correlation of both dimensions was positive and significant ($F = 278.75, R = 0.87, ***P < 0.001$). Saucedo and Monteforte (1997) and Saucedo et al. (1998) considered wet weight acceptable as identification tag for individuals this size/age. In our study, similar overall reproductive stage among individuals would have contributed to reduce wet weight outliers. Respiration rate (Rr) was analyzed as index of recovery within and between drugs, and related to CTRL, through the formula:

$$Rr(\mu\text{L L}^{-1} \text{O}_2 \text{g}^{-1} \text{min}^{-1}) = [(OxT_0 - OxT_n)/\text{Wet weight}]/T_n$$

OxT₀ and OxT_n are starting and subsequent YSI records in mg L⁻¹ of oxygen, converted to μL L⁻¹ of O₂ (Lehninger 1982). This unit was convenient for the strategies of data management and definition of plot patterns in which the purposes of this work were based. Wet weight (in g) is the individual tag, and T_n is the corresponding recovery time stage expressed in logs (T) of 10 or 20 min. Response profile was explored with median Box-Whiskers tests on raw Rr data (Fig. 1), this underlines individual behavior and its influence on profiles which represents important criteria for therapy evaluation. Slope attributes and intercept of data sets were obtained by regression methods. Their reliability was inferred with one-way ANOVA F and corresponding regression coefficient (R). Covariance analyses were calculated to assess differences in slopes ($F_{calc} > F_{tab}, *P < 0.05$) or elevations ($F_{calc} < F_{tab}, P > 0.05$) (Table 2). The influence of recovery time on effects of dose, exposure time, and their interactions, was examined with three-way ANOVA (time × dose × exposure) and compared with CTRL based on their respective *P* level of significance (Table 3). To recognize main effects of dose and exposure time within drug, the post-hoc HSD Tukey sequence was applied with recovery time as contrast background. Further elements for therapy evaluation were provided by two-way ANOVA and HSD Tukey on Rr records at the start and end of each experiment (Table 4) (Sokal and Rohlf 1981, Dillon and Goldstein 1984, Zar 1999, CSS-Statistica 1999). Survival was monitored 6 mo in field culture installations.

RESULTS

Blank respiration chambers remained stable in all sessions between 6.55 and 6.70 mg L⁻¹. Calibration of YSI meters was seldom needed. Untreated (CTRL) *P. mazatlanica* presented highly significant negative correlation of Rr over time ($F = 121.2, R = 0.85, ***P < 0.001$). Intercept was 0.20 μL L⁻¹ g⁻¹ min⁻¹ and slope -0.004 (Table 2); the *P* level of "recovery" time layed on 10⁻¹⁸ (Table 3). Overlap of time-logs in CTRL occurred between T40 and T50 (Fig. 1). Final record of Rr at T50 was 0.05 ± 0.01 μL L⁻¹ g⁻¹ min⁻¹ (Table 4). Some individuals at T30 also had low Rr, whereas T10 was grouped highest (Fig. 1). Significant negative correlation was also detected for pearl oysters treated with PP and MS ($F = 28.39$ and $177.62, ***P < 0.01$), whereas for QN the correlation was positive ($F = 114.69, **P < 0.01$). The general response profile in all drugs was highly dependent on recovery time with *P* levels of 10⁻¹⁰ to < 10⁻²⁴; particular patterns were noted among treatments and in comparison with CTRL (Fig. 1, Tables 2–4). Trials into PP and MS seemed to share a common model near to CTRL, whereas notable differences were detected in pearl oysters exposed to QN (Fig. 1). R coefficient was low in PP and better in MS (0.37 and 0.74, respectively), whereas in QN was 0.61; CTRL had 0.85. This review indicated intrinsic effects of

TABLE 1.

Experimental design of anesthetic therapies with three drugs.

Drug Dose	Exposure Time	Recovery Time
	(min)	(min)
Propylene phenoxetol (PP) 1 mL, 3 mL, 5 mL		10
		20
Finquel MS-222 (MS) 2.5 mg, 5 mg, 7.5 mg	30	30
		40
Quinaldine (QN) 15 mL, 30 mL, 45 mL	60	50
		60
Control (CTRL) (<i>n</i> = 18)	Untreated (<i>n</i> = 9 sms/Exp, T.)	10 to 50

Trials under treatment (dose, exposure time) consist of *n* = 18 individuals each. CTRL specimens were divided in groups of *n* = 9 for each "exposure" time. Experimental sessions were not simultaneous: CTRL was first, PP second, MS third, and QN last.

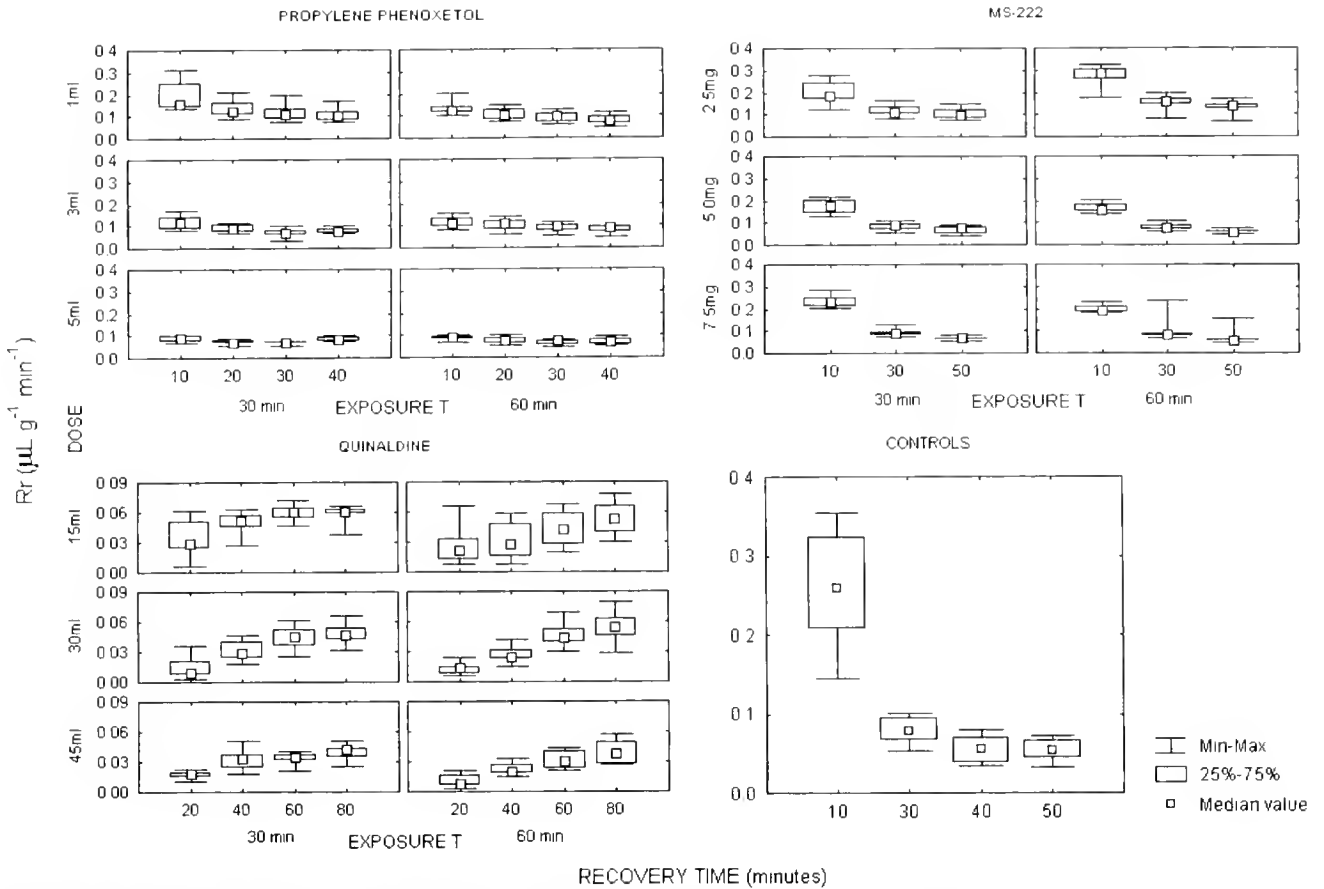

Figure 1. Median Box-Whiskers plot of recovery profiles measured by Respiration rate in *Pinctada mazatlanica* under three relaxation therapies (PP, MS, and QN) in comparison with a model (CTRL).

drug in the recovery profiles of *P. mazatlanica*. Dose and/or exposure time delineated particular patterns within and between drugs. Results in CTRL were essential to understand these profiles. We examined each experiment.

Propylene Phenoxetol

Significant negative correlation of Rr related to recovery time was confirmed for most cases (** $P < 0.01$). In these, Rr intercept was from 0.12 to 0.21 $\mu\text{L L}^{-1} \text{g}^{-1} \text{min}^{-1}$, R settled into 0.52 and 0.64, and slope into -0.003 and -0.001 . Individuals at dose of 5 mL in both exposure times were exceptions (Fig. 1, Table 2). The regression test and R values seemed sensible to individual differences within PP, particularly in these exceptions. However, the overall Rr range was lower than in MS or CTRL (Fig. 1, Tables 2 and 4) and tendency to horizontality seemed more notable (Fig. 1, Table 2). The covariance analysis indicated highly significant differences in slopes ($F_{\text{calc}} = 4.40 > F_{\text{tab}} = 2.27$, *** $P < 0.001$) and elevations ($F_{\text{total}} = 33.55 > F_{\text{tab}} = 2.81$, *** $P < 0.001$). The effect of dose had important influence in these estimates, recovery time shortly followed as evident background, whereas exposure time had less significance; P level of dose and exposure time was similar as in other drugs (Table 3). Interaction of dose with exposure time, and of recovery time with dose also had rather equivalent significance as in MS and QN, while nonsignificant influence of recovery time was detected on the effect of exposure time or the combination of all effects (Table 3). Dose of 5 mL at both exposure times tended to horizontality from T10. Recovery time had no

influence as all-effect, confirming a common background response profile for all PP treatments without major Rr outliers (Fig. 1, Table 3). The three-way post-hoc HSD Tukey test with contrasted recovery time indicated that pearl oysters had low Rr in high dose or long exposure. On the contrary, low dose and short exposure introduced data dispersion, high intercept value and more slope inclination (Fig. 1, Table 2). Exposure for 60 min promoted homogeneity of recovery profiles for all doses; the general Rr range in each time stage tended to be low and narrow (Fig. 1, Tables 2 and 4). Pearl oysters exposed for 30 or 60 min into 5 mL had stable Rr during recovery, with nearly horizontal slope and low intercept value (Fig. 1, Tables 2 and 4). The two-way ANOVA-HSD Tukey at T10 of recovery indicated highly significant differences of Rr values for dose ($F = 15.22$, *** $P < 0.001$) but not for exposure time ($F = 3.54$, $P > 0.05$), neither their interaction ($F = 2.78$, $P > 0.05$). In this stage, individuals treated with higher dose and/or longer exposure time had lower and narrower Rr, coinciding with low intercept and almost horizontal slope (Fig. 1, Table 4). At T40 there was no effect of dose ($F = 2.8$, $P > 0.05$), whereas exposure time had moderated importance ($F = 5.23$, * $P < 0.05$). Their interaction was not significant ($F = 2.0$, $P > 0.05$). In this stage, differences of Rr values were significant only between batch of 1 mL–30 min (highest Rr) and the one of 5 mL–60 min (lowest Rr) (Fig. 1, Table 4). Survival was 100%.

MS-222

Correlation of Rr over time was negative and significant in all treatments (*** $P < 0.001$). The intercept varied between 0.18 and

Significance of the regression ANOVA F is * $P < 0.05$, ** $P < 0.01$, and *** $P < 0.001$. The post hoc HSD Tukey considered recovery time as contrast factor. Different indexes denote significant differences at $P < 0.05$.

0.30 $\mu\text{L L}^{-1} \text{g}^{-1} \text{min}^{-1}$ and R between 0.71 and 0.90. Slope values predominated in -0.003 and -0.004, with exception of one only case of -0.002 (Fig. 1, Table 2). The overall range of R coefficient appeals for more uniform variation of Rr within MS, frequently over 0.79 (Table 2), but this may not be clinically conclusive. Covariance analysis revealed conservative differences in slopes ($F_{\text{calc}} = 2.32 > F_{\text{tab}} \approx 2.27$, * $P < 0.05$) while elevations appeared more diverse ($F_{\text{total}} = 28.31 > F_{\text{tab}} \approx 2.81$, *** $P < 0.001$) (Fig. 1, Table 2). The effect of time in the recovery profiles under MS seemed most important than in other drugs (Table 3). Dose, exposure time, and their interaction were significant with similar P level as in PP and QN. All-effect interaction was significant but at lowest P level; although code mixing was frequent at T50, overlap order of T30 and T50 occurred seldom within sets and most cases

of T10 tended to group at higher Rr (Fig. 1). This suggests that the influence of recovery time was probably overestimated: the inclusion of a T40 log would have increased overlapping events between this and T50 (as in PP and CTRL), while the inclusion of a T20 would have scarcely affected the first (higher Rr) position of

T10 logs (i.e., T10 of datasets 2.5 mg–60 min and 7.5 mg–30 min). The sudden rise of Rr at T30 and T50 in trial of 7.5 mg–60 min corresponds to three specimens (Fig. 1), apparently provoked by mechanical disturbances (noise or motion). The contrasted three-way HSD Tukey indicated that pearl oysters had high Rr and dispersion at lower doses for both exposure times. The experiment of 2.5 mg–60 min presented highest slope and intercept value with dispersion toward high Rr. Individuals placed into 5 mg for 30 and 60 min had less variation in their recovery profile, also coinciding with lowest intercept and “average” -0.003 slope. Longer exposure time in doses of 5.0 and 7.5 mg apparently contributed to decrease individual differences; however, this effect was only observed when comparing early recovery stages of both exposure times (Fig. 1, Tables 2 and 4). A related analysis with elimination of outliers in T30 and T50 for 7.5 mg–60 min dataset did not alter the similarity of trials with 5.0 mg for both exposure times. The two-way ANOVA-HSD Tukey test applied at T10 and T50 of recovery supports the above. In the first time-log, the effect of dose was highly significant ($F = 14.95$, $***P < 0.001$), so was its interaction with exposure time ($F = 11.19$, $***P < 0.001$), while this last apparently had no influence ($F = 1.19$, $P > 0.05$); in the second time-log, only the effect of dose was significant ($F = 23.97$, $***P < 0.001$). At T10, individuals of 7.5 mg–30 min and 2.5 mg–60 min had significantly higher Rr (also higher intercept and slope inclination) than those treated with 5 mg at both exposure times (lower intercept and “average” slope) (Tables 2 and 4). At T50, pearl oysters placed into 2.5 mg during 30 and 60 min of exposure had higher Rr, while the rest were relatively similar (Table 4). Elimination of outliers 7.5 mg–60 min at T50 made no impact in this pattern. Survival was 100%.

Quinaldine

All treatments had significant positive correlation of Rr over time ($**P < 0.01$). R coefficient varied between 0.50 and 0.88, intercept from 0.001 and $0.03 \mu\text{L L}^{-1} \text{g}^{-1} \text{min}^{-1}$, and slope from 0.0003 to 0.0007 (Table 2). Overall range of R values suggests slightly better reliability of this predictors than in PP. Besides, the absolute variation of Rr within QN was narrow and had lower values than in other drugs and CTRL, almost throughout the experiment (Fig. 1). The covariance analysis indicated similarity of slopes ($F_{\text{calc}} = 1.84 < F_{\text{tab}} \approx 2.27$, $P > 0.1 < 0.25$), whereas elevations were highly different ($F_{\text{total}} = 58.54 > F_{\text{tab}} \approx 2.81$, $***P < 0.001$). The effect of recovery time was very important in this pattern at P level of 10^{-24} . Similar to other drugs and CTRL, Rr of pearl oysters under QN followed a main background profile related with time, although in positive direction. Dose also had strong influence but at relatively less extent than in PP or MS, whereas exposure time and its interaction with the former had similar P level as in other drugs. All-effects interaction was not significant (Table 3). Overlap of time-logs occurred in all datasets for T60 and T80 min of recovery (Fig. 1), but in some trials this started earlier coinciding with larger individual differences of Rr (i.e., from T20 in 15 mL–60 min, and from T40 in 45 mL–30 min). Cases of T20 tended to group in last place (low Rr) except those of 15 mL (Fig. 1). The three-way HSD Tukey with recovery time as contrast suggests significant differences between lowest Rr in 45 mL–60 min and highest in 15 mL–30 min, coinciding respectively with low and high intercept and similar slope. Differences of recovery profiles in treatments with 30 and 45 mL at both exposure

times were not substantial. Response homogeneity among individuals seemed to increase with dose, while variation of Rr increased with longer exposure times. R value of each batch also indicate individual differences in 15 mL at both exposure times, while moderate to low dispersion was detected for other treatments (Table 2). However, the general trace of Rr values over recovery time did not tend to dispersion declining as in other drugs or CTRL (Fig. 1). In some treatments, individual differences remained rather constant, either in low Rr such as those of 45 mL in both exposure times or high Rr like 15 mL in both exposure times. Dispersion increase seemed more evident in dose of 30 mL at both exposure times (Fig. 1, Table 2). The analysis at T20 and T80 of recovery stands for this pattern (Table 4). At T20, the effect of dose was significant ($F = 9.12$, $***P < 0.001$), while not the effect of exposure time ($F = 2.39$, $P > 0.1$), neither their interaction ($F = 0.37$, $P > 0.5$). Batches of 15 mL–30 min and 15 mL–60 min had higher Rr but dispersion weighed toward low values in the first and high values in the second (Fig. 1); difference between these was not significant. Significantly low Rr oscillated between 0.011 and $0.014 \mu\text{L g}^{-1} \text{min}^{-1}$ at T20, the first—and lowest of all drug sets—corresponding to 45 mL–60 min. At T80, the effect of dose was significant ($F = 6.44$, $**P < 0.01$), whereas exposure time had no effect ($F = 0.003$, $P > 0.5$). Their interaction was not significant ($F = 0.82$, $P > 0.1$). Differences of Rr were evident only between 15 and 45 mL in the same exposure time (30 min). The first started (T20) and finished (T80) with significantly higher Rr; it also presented the highest intercept value and similar slopes for each exposure time but also the lowest R value. The second had lower Rr, coinciding with low intercept and the most horizontal slope of each exposure time; R values were higher than in doses of 15 mL. Apparently, individuals treated with 45 mL still had low Rr at T80 (Fig. 1, Tables 2 and 4). There was no mortality during the experiment.

Mortality in Field Culture

The generation of *P. mazatlanica* corresponding to this study accumulated 4% of average mortality in six months, with frequent monthly zeroes in many containers. This behavior is normal for the species (Monteforte et al. 2000). In general, the current experiment did not diverge from this pattern. Mortality after 6 mo was: 1 individual for CTRL and QN, respectively, and 2 for PP and MS, respectively. We noted that all incidence of mortality occurred in the first month of field culture. Survival was 100% until the sixth month.

DISCUSSION

Evaluation of presurgery therapies for *P. mazatlanica* was based on the effect of dose, exposure time, and interactions within and between drugs, and their comparison with the model pattern of CTRL. These therapies were explained as index of recovery or “stress level” by the position of intercept and Rr value at starting T, by the pattern of dispersion and range of individual differences during recovery, and by the attributes of slope, including time needed for apparent stabilization toward a “common” Rr value (Fig. 1, Tables 2 and 4). Stress has been interpreted as physiologic response involving particular meaning when related to anesthetics. Records of corticosteroids have been used in studies regarding stress indexes for several species of fish. In most cases, drugs themselves appeared as stressors and did not reveal special advan-

tages to prevent physiologic stress responses (Wagner et al. 2002). In our work, the monitoring of Rr was considered a reliable index to interpret the response of *P. mazatlanica* under different therapies. The model pattern in CTRL started at initial T with differential activity, most individuals into conditions of high intercept and Rr value, followed by rapid decrease of dispersion and Rr value until apparent stabilization at about 0.05 mL L^{-1} in T50 (Fig. 1, Tables 2 and 4). Significance of recovery time in this model was on 10^{-18} P level (Table 3). Pearl oysters under therapy also were strongly influenced by recovery time but with wide differences of P level from 10^{-10} to $< 10^{-24}$ between drugs (Fig. 1, Table 3). This suggest that *P. mazatlanica* had a dynamic overall response during recovery acting as main background variation and strongly affected by time, while dose, exposure time, and their interactions contributed to arrange particular patterns for each therapy regarding the CTRL model. Dose had equivalent P level in PP and MS, and relatively less for QN; the effect of exposure time and interaction with dose were also grouped (Table 3). Differences in significance P level of recovery time may reside on the nature of drug components and their specific influence on mechanical and physiologic functions of also specific body parts (Iversen et al. 2003). In these terms, the appraisal of relationships among treatments and therapy profiles was supported with a cluster analysis of the multiple covariance matrix using complete linkage rule and Euclidian distances (Sokal and Rohlf 1981, Dillon & Goldstein 1984, Zar 1999, CSS-Statistica 1999). As expected, the effect of drug appeared as important discriminant between treated and untreated individuals (Fig. 2). Main clusters distinguished recovery profiles based on activity level, from higher in CTRL to lower in QN (Fig. 1, Tables 2 and 4). CTRL stated at 60% of definition. Trials into PP, MS seemed to share a common model near to CTRL: high activity and/or dispersion of Rr in early phase, dispersion declining toward low Rr as recovery progressed, and apparent stabilization at about 50 min. Aside their different slope attributes, pearl oysters exposed to QN had no evident dispersion declining of Rr through time as in the previous drugs and CTRL; however, overall absolute variation remained narrow and values were much lower in QN. Stabilization was considered present at 80 min (Fig. 1). The "stress" cluster was formed by all MS datasets and PP 1 mL–30 min and it remained to 44%. Pearl oysters in these trials presented lower Rr dispersion than CTRL and also a tendency to decrease over time, however, their recovery profile appeared similar in sev-

eral elements that suggest unadequate relaxation (Fig. 1, Tables 2 and 4). Notably, trial of PP 1 mL–30 min joined this cluster at 16% apparently because it had the highest intercept, slope, and covariance values within this drug. Its attachment to "MS" cluster was on trial MS 2.5 mg–30 min, as confirmed by their similar profiles (Figs. 1 and 2, Tables 2 and 4). Within "MS," clusters were apparently defined by the dispersion pattern of Rr and its position in the plot (intercept and Rr value at initial T). The cluster formed by trials with 5 mL at both exposure times and trial 7.5 mg–60 min indicate homogeneity of Rr toward low-activity profiles (i.e., low intercept, moderate slope, dispersion decrease, and low Rr value at final T) (Fig. 1, Tables 2 and 4). Components of cluster "PP" suggest that higher dose promoted low disturbances of Rr. Treatments of 5 mL in both exposure times joined at 4% and remained as separate cluster up to 20%. Lower dose of this substance and/or lesser exposure time provoked a similar response pattern as in the "stress" cluster, this was notable in the mentioned trial 1 mL–30 min of PP (Figs. 1 and 2; Tables 2 and 4). With this exception, both trials of 3 mL and the one of 1 mL–60 min stayed as cluster of higher activity within PP to 12% (Fig. 2). Cluster "PP" joined the "QN" nearly at 40% with the trials of low-profile PP 5 mL of both exposure times and stayed separated from the previous "CTRL" + "MS" through 100%, however, cluster "QN" remained defined only at 10%. The recovery profile of pearl oysters treated with QN had very low intercept position and Rr value at starting T, and lower range during recovery in comparison with the other experiments. Slope was nearly horizontal but stabilization was considered present later than in CTRL and other treatments. Components of cluster "QN" were apparently defined by the dispersion pattern of Rr and intercept. Low-profile response (lowest of all trials) could be considered for clusters of 45 mL, where dispersion of Rr during recovery was narrow but it remained rather constant. The QN trial of 15 mL–60 min was apparently attached to the former for its tendency to low intercept and constant dispersion, although this last was larger than in doses of 45 mL. Lower dose or exposure time under QN promoted tendencies to increase Rr dispersion; these trials compose the high-activity area within cluster "QN," although their range value remained lower than in CTRL, MS, and PP (Figs. 1 and 2). The overview suggests that resemblance or difference of recovery profiles in CTRL pearl oysters and those under treatment were principally defined during early phases. Trials with MS and PP coincided in having a negative correlation over time indicating recovery from stressed state, but relatively less than in CTRL. Specimens placed into QN had slow recovery from depressed activity toward higher Rr (Fig. 1). This suggest that drugs were no stressors for *P. mazatlanica*. It was also evident that the overall projection of recovery profiles moves toward a Rr of $0.05 \mu\text{L g}^{-1} \text{ min}^{-1}$, assumed from measures in controls at T50 (Fig. 1, Table 4). Specimens under PP and MS had rather similar end Rr as in CTRL at T50, but it took longer time for those exposed to QN. Even at T80, a good proportion of pearl oysters still were less active than CTRL and some other drug trials. However, it would be inexact to consider these end values as probable standard rate for the species because particular studies should be previously applied. This information is primary when the physiologic response of an organism to environmental changes is measured or interpreted through some index of stress over time. In marine bivalves, stress has been explained by functions such as clearance and filtration rate, heart beat, components of excretion, oxygen consumption, and so forth. (Bayne et al. 1976a, Bayne et al. 1976b). This last function is implicit in the recovery index used

Figure 2. Hierarchical tree with multiple covariance analyses of experimental datasets and CTRL. Clusters are defined by Euclidian distances and complete linkage.

in this work. Bayne et al. (1976a) stated that *Mytilus edulis* under starvation rapidly arrives to standard respiration rate when gametogenesis is completed and energy reserves of the body are at the minimum. In this context, we assumed that all individuals entered the current experiment at a similar level of activity. Nevertheless, the comparative information of oxygen consumption in bivalves is controversial due to the variety of measurement methods, units used, and experimental designs (Shumway 1982). Concerning pearl oysters, Yukihiro et al. (1998) reports Rr (R in the cited work) of 0.857 and 1.039 mL O₂ oyster⁻¹ h⁻¹ in *P. maxima* and *P. margaritifera*, respectively, as intercept values from a significantly inclined and positive regression of Rr, or R, over dry weight. The authors considered these species as exceptional in having the highest indexes of energy flux recorded for bivalves. Saucedo et al. (2003) defined respiration rate of 0.4 to 0.8 μmol g⁻¹ h⁻¹ in fed and acclimatized *P. mazatlanica* between 18 C and 33 C. With these considerations, presurgery treatments in *P. mazatlanica* are difficult to explain in terms of physiologic response, and this lack of information calls for such studies. Aside from the intrinsic effect of chemicals even into complex body functions (Wagner et al. 2000; Eversen et al. 2003), the induction surgery would initiate hardly known immunologic processes in pearl oysters (i.e., Ortuño et al. 2002 in *Sparus aurata*). Norton et al. (2000) associated the use of PP with total failures in round pearl induction on *P. margaritifera* (mortality + nucleus rejection).

CONCLUSIONS

The best therapies in *P. mazatlanica* should sustain a nearly horizontal slope and low Rr-intercept during recovery; homogeneity of individual response is also important. These observations may comply with other species of pearl oysters. In real practice, the use of QN at doses of 45 mL eased the surgery for round pearl due to adequate and longer relaxation of specimens, but protection equipment is recommended. Treatments with 5 mL of PP were also acceptable, which suggest that higher dose and/or exposure time under this drug would provoke a "QN"-like response profile in this species, probably with shorter recovery time. Doses of MS-222 between 5 and 7.5 mL at 60 min of exposure could be used in *P. mazatlanica* for Mabé implants only. All specimens treated with this therapy had reasonably relaxed their abductor muscle, and mantle retraction was none or very slow; however, we noted about 70% of them arriving with contracted gonadal tissue and ligaments and/or foot muscle, which introduced a problematical approach to the insertion site. Based on our results, there is no evidence that longer exposure and/or higher dose of MS-222 might lead to low-activity profiles. Aside from the need for studies regarding the physiologic response profiles and relationship with functions of body parts, tolerance tests to these three drugs are important. In this experiment, mortality could not be attributed to any drug into the effective ranges of therapies. Incidence of mortality in field culture suggest handling effects.

EFFECTS OF SALINITY AND TURBIDITY ON THE FREE AMINO ACID COMPOSITION IN GILL TISSUE OF THE PACIFIC OYSTER, *CRASSOSTREA GIGAS*

NAM-HYUN LEE,¹ KYUNG-NAM HAN¹ AND KWANG-SIK CHOI^{2,*}

¹Department of Oceanography, College of Natural Science, In-Ha University, 253 Yonghyun-Dong, Nam-Gu, Incheon 402-751, KOREA; ²School of Applied Marine Science, College of Ocean Science, Cheju National University 1 Ara 1-Dong, Jeju, 690-756 Korea

ABSTRACT Effects of salinity and turbidity stresses on free amino acid (FAA) composition in *Crassostrea gigas* was investigated using high performance liquid chromatography. Oysters were exposed for 2 to 5 days to low salinity (LS, 7‰), normal (control, 30‰), high salinity (HS, 39‰), and high turbidity in normal salinity (HT, 30‰, 0.326 g kaolin clay/l). Levels of aspartic acid, glutamic acid, serine, glycine, β-alanine, taurine, and L-alanine in the gill tissues were then monitored using a HPLC. Taurine and glycine were the two major contributors to the total FAA in gill tissues of oysters collected from fields, ranging from 200.7–324.7 and 42.9–69.0 μmol/mg dry tissue. On day 2, total FAA in HS and HT was significantly higher than the levels in the control and LS; taurine and glycine levels in HS and HT were significantly higher than the levels of the controls and LS ($P < 0.05$). In contrast, most FAA levels in LS had dropped except for glutamic acid, glycine, and β-alanine; β-alanine level of oysters in LS on day 2 was about 10-fold higher than the control. Aspartic acid and Glutamic acid levels in HT on day 2 were significantly higher than the level observed in HS, LS and control ($P < 0.05$). From day 2 to 5, total FAA in the control increased 11.4% whereas total FAA in HS, LS, and HT decreased 17.3%, 21.6%, and 19.3% respectively. Aspartic acid and glutamic acid levels in the control also increased 29.1% and 50.6% between day 2 and 5 whereas the levels in HS, LS, and HT dropped dramatically, from 47.1 (HT) to 72.0% (LS) in case of aspartic acid and 53.5 (HS) to 68.5% (LS) in glutamic acid. Response of FAA composition in the gill tissues to salinity and turbidity stress was unique in this study, suggesting that FAA analysis is a useful tool to diagnose environmental stress to *C. gigas*, as was observed in *C. virginica*.

KEY WORDS: free amino acids, *Crassostrea gigas*, salinity, high turbidity, stress, HPLC, oyster

INTRODUCTION

Marine invertebrates contain very high levels of free amino acids (FAA) in their tissues and fluids, being 100 to 1000 times higher than those found in the extra-cellular fluid (Gilles 1972; 1979, Bayne et al. 1979). The FAAs are involved in a wide variety of biochemical and physiologic processes, and they are often monitored as a stress indicator in marine invertebrates under natural or man-made disturbances (Lynch & Wood 1966; Briggs 1979; Powell et al. 1984; Burton 1992). Epidermal tissues of marine bivalves in particular contain high level of FAAs, and the level of FAAs in the tissues often indicates their physiologic and nutritional status of an animal (Feng et al. 1970; Biondi & Noviello 1978; Sakaguchi & Murata 1989; Paynter et al. 1995). It is also well known that intracellular FAA in bivalve tissues are used in cellular volume regulation. An increase or decrease in salinity often results in an increase or decrease of FAA level in the tissues (Lynch & Wood 1966; Baginski & Pierce 1977; Shumway & Gabbott, 1977; Powell et al. 1982; Ellis et al. 1985).

C. gigas is an estuarine bivalve inhabiting intertidal to shallow subtidal areas in Korea, Japan, and China where they are commercially raised. The oysters are particularly abundant in coastal estuarine areas where fluctuations of temperature and salinity, as well as man-made pollution, often exert significant physiologic impacts (Feng et al. 1970; Livingston 1985; Tirard et al. 1997). *C. gigas* tissues are enriched with amino acids, and the levels of free amino acids in the tissues often reflect environmental changes as well as seasonal variations (Sakaguchi & Murata 1989). Although there are many reports on the effects of environmental changes on *C. gigas* physiology as measured with various biochemical assays, studies on the effects of environmental changes on the FAA pool are rare despite the commercial importance of this species. This

study attempts to evaluate the effects of salinity and turbidity on the FAA pool of Pacific oysters.

MATERIALS AND METHODS

Oysters used in the experiment were collected from Kamakman Bay on the south coast of Korea, where the oysters are commercially cultured using the hanging culture system. Salinity in this bay fluctuates between 28‰ and 33‰, and the visibility of the water varies from 1.5–3 m annually (Hyun et al. 2001). Oysters of 8–12 cm long and 10–15 g wet tissue weight were collected from oyster grow-out hanging lines placed at a depth between 1 and 4 m below the surface. The gill tissues of 13 oysters were excised *in situ* and frozen immediately using dry ice and subjected to FAA analysis. The amino acid composition of the control oysters collected from Kamakman Bay were compared with that of other oysters collected from an intertidal area at Daechon on the west coast of Korea where salinity varies 25‰ to 35‰ annually.

For the experiment, oysters were placed in static 50-L glass tanks filled with normal salinity seawater (30‰). After a 2-day acclimation period, the following experimental conditions were applied: (1) control at 30‰; (2) high salinity stress at 39‰ (HS); (3) low salinity stress at 7‰ (LS); and (4) high turbidity (HT) stress created with kaolin-clay with a constant concentration of 0.323 gm/l in 30‰ seawater according to Powell et al. (1982). A set of 20 oysters was placed in each 50-L glass tank, and the water was continuously stirred and aerated during the experimental period. Seawater in the tanks underwent a 100% water change twice daily. To maintain constant high turbidity in the tank, the kaolin concentration was checked four times a day and a proportional amount of clay was added if necessary.

On days 2 and 5, seven oysters were collected from each experimental tank to measure FAA in their gill tissues. Oysters were opened and gill tissues removed, weighed, and stored at –70 °C until analyzed. Dry weight of the gill tissue was estimated from the

*Corresponding author. E-mail: skchoi@cheju.ac.kr

empirical relation; dry weight = wet weight of gill tissue \times 0.196 (Choi et al. 1993). The oyster gill tissue was homogenized in phosphate buffer (pH 7.3) using a mortar and ultrasonifier at 4 \square . The homogenate was centrifuged and the supernatant collected for analysis. The supernatant was then treated with trichloric acid (TCA), from 10%–50%, to precipitate proteins and nucleic acids (Powell et al. 1982). TCA treated samples were centrifuged to remove protein and the supernatant containing FAA was harvested. TCA in the supernatant was then removed using six applications of ether. Types of FAA in the samples were determined with HPLC using methanol-acetate as a solvent. Orthophthaldialdehyde (OPA) was used as the detecting compound for identification and quantification of FAA. Aspartic acid, glutamic acid, serine, β -alanine, L-alanine, glycine, and taurine were analyzed from the FAA pool in the oyster gill tissues and finally expressed as $\mu\text{mol FAA/g}$ dry tissue weight.

RESULTS

FAA Composition of Oysters Collected *In Situ*

Amino acid composition in gill tissues of control oysters is summarized in Table 1. Among the seven amino acids analyzed, taurine and glycine were the most abundant amino acids in the gill tissues sampled from the Daechon and Kamakman Bay. These two amino acids accounted for more than 70%–80% of the free amino acids measured in the oysters.

Changes in FAA Composition in Oysters in Control Tank

Table 2 summarizes changes in the FAA composition of oysters held in the control tank (30‰) for 2 and 5 days. As observed in wild oysters, taurine and glycine were the most abundant compounds that accounted for more than 82% of total FAAs in oysters in the control tank for 2 days. In addition to taurine and glycine, L-alanine, aspartic acid, and glutamic acid were present in the oyster tissues at levels of 20.14, 16.72, and 14.23 $\mu\text{mol/g}$ dry tissue weight respectively. In contrast, serine and β -alanine levels in the control oysters were <10 $\mu\text{mol/g}$ dry tissue. After 5 days in the control tank, glutamic acid levels increased by 50.6% relative to the level at day 2. In contrast, β -alanine and L-alanine levels at day 5 dropped by 31.1% and 32.5%.

FAA Changes in HS Tank

All FAA levels in oysters in the increased salinity at day 5 were lower than the FAA levels in oysters at day 2, except serine.

TABLE 1.

FAA composition of oyster gill tissues collected from Kamakman Bay and Daechon (N = 26). Numbers in parenthesis represent standard deviation. Unit = $\mu\text{mol/mg}$ dry tissue weight.

	Daechon	Kamakman Bay
Aspartic acid	16.5 (2.5)	18.5 (2.1)
Glutamic acid	28.3 (7.7)	34.2 (6.8)
Serine	13.2 (1.5)	10.1 (1.7)
Glycine	69.0 (20.6)	42.8 (8.7)
β -Alanine	15.9 (3.3)	5.2 (0.1)
Taurine	200.7 (48.3)	324.4 (45.1)
L-Alanine	37.3 (11.0)	29.7 (7.2)
T/G ratio	2.9	7.6
TOTAL	380.8 (91.9)	464.8 (60.6)

Aspartic acid, glutamic acid, glycine, and β -alanine levels dropped by –54.1%, –53.5%, –55.8% and –36.1% respectively. Contrary to other FAAs, taurine levels between day 2 and day 5 remained largely unchanged (see Table 2). Due to the taurine, total FAAs had only dropped –17.3% between day 2 and day 5 in the high salinity tank.

Compared with the control oysters, total FAA levels in oysters held in HS tank for two days were found to be 1.61 fold elevated (Table 3). Particularly, the glycine level in the oysters at Day 2 was much higher, by a factor of 2.90, than the level in oysters held in the control tank (30‰) at day 2. It was also noticed that the β -alanine level in HS at day 2 was 3.05-fold higher than the level in oysters held in the control. The taurine level of oysters in the tank was also 1.47-fold higher than the level of control oysters. In contrast, the serine level remained largely unchanged at day 2. By day 5, aspartic acid and glutamic acid levels had dropped by a factor of 0.60 relative to the control oysters. However, the β -alanine level of the oysters in the LS tank was much higher, a factor of 2.83, than the level in the control salinity tank. Serine, glycine, and L-alanine levels were also higher than the control oysters at day 5, by a factor of 1.70, 1.53, and 1.63 (see Table 3).

FAA Changes in LS Tank

Between day 2 and day 5 in the LS tank, all FAA levels in the oysters had dropped. Aspartic acid, glutamic acid, glycine, and β -alanine levels fell by 72.0%, 68.6%, 34.6%, and 31.9%. In contrast, taurine, that accounts for more than 70% of the total FAA in the oysters, decreased by only 8.8% (see Table 2).

After 2 days in LS (7‰), the taurine level dropped by a factor of 0.68 compared with the level of the control oysters (see Table 3). Aspartic acid and L-alanine levels in the oysters also decreased by factors of 0.59 and 0.46 relative to the control oysters at day 2. However, the glutamic acid and β -alanine levels were elevated by a factor of 1.85 and 10.36 respectively. At day 5, the total FAA level dropped by a factor of 43% compared with the control oysters at the same time period. Aspartic acid and glutamic acid levels dropped by a factor of 0.13 and 0.39 relative to the control oysters. In contrast, the β -alanine level in oysters at day 5 remained elevated as observed at day 2, 10.23-fold higher than the β -alanine level in the control oysters (see Table 3).

FAA Changes in HT Tank

Between day 2 and day 5, most FAA levels in the oysters dropped more than 30%. Aspartic acid, glutamic acid, glycine, and β -alanine levels dropped by 47.1%, 64.1%, 36.6%, and 30.1% respectively. However, the serine level had risen by 55.9% after 3 days in HT, between days 2 and 5 (see Table 2).

Oysters incubated in the HT tank for 2 days showed a very high level of taurine compared with the control oysters. Taurine level of the oysters was 1.85-fold higher than the level of the control oysters. Other FAA levels were also elevated by more than 30% for 2 days (see Table 3). Aspartic acid and glutamic acid levels also increased by a factor of 2.40 and 2.78 relative to the control oysters. Total FAAs of the oysters were also 1.81-fold higher than the total FAAs of the control oysters at day 2. At day 5, total FAA level in the high turbidity tank remained elevated by a factor of 1.31. The taurine level of the oysters at day 5 was 1.38-fold higher than the taurine level of the control oysters. In contrast, glutamic acid levels in the oysters at day 5 were lower than those of the control oysters by a factor of 0.66 for the same length of time.

TABLE 2.

Concentration of amino acids and their percent changes in the FAA pool in controlled and treated oysters at two and five days. Each concentration value represents the mean of seven samples (unit = μmol FAA/g dry tissue). % change = (Day 5/Day 2) - 1.

Amino Acid	Normal (Control, 30‰)			High Salinity (HS, 39‰)			Low Salinity (LS, 7‰)			High Turbidity (HT, 0.326g koalin clay/l)		
	Day 2 (N = 7)	Day 5 (N = 7)	% Change	Day 2 (N = 7)	Day 5 (N = 7)	% Change	Day 2 (N = 7)	Day 5 (N = 7)	% Change	Day 2 (N = 7)	Day 5 (N = 7)	% Change
Aspartic Acid	16.7	21.6	29.1	28.1	12.9	-54.1	9.8	2.8	-72.0	40.1	21.2	-47.1

DISCUSSION

FAA Composition in Field Oysters

Table 1 indicates that taurine is the most abundant FAA in the control oysters collected from Kamakman Bay, followed by glycine. Taurine and glycine account for 52% and 18% of total FAAs respectively in oysters collected from Daechon. Sakaguchi and Murata (1989) also reported that taurine and glycine are the most abundant FAAs in cultured *C. gigas*. High levels of taurine in the FAA pool also have been reported from various marine bivalves; it is believed that most marine bivalves use taurine in osmotic volume regulation (Sansone et al. 1978; Powell et al. 1982; Lynch & Wood 1966; Feng et al. 1970). Taurine levels in oysters col-

lected from Kamakman Bay were much higher than the levels observed in Daechon oysters, whereas the glycine level of Kamakman Bay oysters was lower than those from Daechon. Taurine comprises 70% of the total FAA, whereas glycine accounts for only 9% in Kamakman oysters.

Different FAA levels observed between Kamakman Bay and Daechon oysters could be associated with different levels of tolerance to stress and anoxia during transportation to the laboratory. Daechon oysters were collected from the intertidal zone where the oysters are exposed to the atmosphere twice a day during low tide. In contrast, Kamakman Bay oysters were collected from an oyster farm where oysters were hanged on suspended rope and submerged from 2-5 m below the surface. It is likely that the intertidal oysters from Daechon are better adapted to anoxic condition formed during transportation by closing their valves. Several studies have reported that marine bivalves often exhibit elevated levels of taurine due to an intracellular response to change in extracellular fluid osmolarity (Pierce 1971; Powell et al. 1982; Paynter et al. 1995).

TABLE 3.

Pair-wise comparisons between all treatments with amino acids at Day 2 or 5 listed below each pair. Each number represents a ratio between mean of one treatment to the other

	Oysters Day 2		
	High Salinity vs. Normal	Low Salinity vs. Normal	High Turbidity vs. Normal
Aspartic Acid	1.7	0.6	2.4

Total FAA	1.2	0.6	1.3

Effects of Changes in Environmental Factors on FAA Composition of Oysters

Man-made disturbances such as high concentrations of heavy metals, hydrocarbons, and drilling effluents, as well as natural stresses, such as starvation, decrease or increase in salinity, and parasitism, often alter the composition of FAAs in marine animals (Jeffries 1972; Pecon & Powell 1981; Roesijadi & Anderson 1979; Widows et al. 1982; Bayne et al. 1976; Kendall et al. 1985; Paynter et al. 1995) as well as the protein synthesis rate (Choi et al. 1994; Tirard et al. 1997). However, the response of the animals in terms of internal FAA change varies with different environmental or natural stresses. Hyper-osmotic, hypo-osmotic, and high turbidity stresses were applied to *C. gigas* in the present study. Oysters exposed to high salinity and high turbidity stress showed a remarkable increase in total FAA for the first 2 days (see Tables 2 and 3).

Other studies have also reported elevated FAA levels in marine bivalves exposed to hyper-osmotic conditions for a short period (Powell et al. 1982; Lynch & Wood 1966). *C. virginica* exposed to high salinity (38‰) for 2 days showed elevated total FAAs. Glycine, alanine, and β -alanine levels were elevated compared with the control oysters (Powell et al. 1982). *C. gigas* in this study also

showed a remarkable increase in glycine, L-alanine, and β -alanine levels when treated with high salinity stress. Baginski and Pierce (1977) also observed elevated alanine and glycine levels in *Modiolus demissus* (= *Geukensia demissa*) 1 to 3 days after holding the mussels in a hyper-osmotic environment. Accumulation of alanine and glycine during hyper-osmotic stress also has been reported for the mussels, *Mytilus edulis* and *Geukensia demissa* (Deaton et al. 1985; Deaton 2001). The increased FAA levels observed in the oysters held in the high salinity tank for the first 2 days are due to volume regulation by the cells of the oysters as reported in other marine bivalves (Deaton et al. 1985).

Oysters exposed to high turbidity water for 2 days also showed a remarkable increase in the FAA levels. Compared with the control oysters, all levels of FAAs in the gill tissue of those oysters were elevated for the 2 days of immersion in highly turbid water. However, the pattern of elevation in FAA is somewhat different between oysters treated with high salinity and high turbidity stress. Taurine, aspartic acid, and glutamic acid levels in the oysters in the high turbidity tank for 2 days were remarkably elevated by a factor of 1.85–2.78 relative to the FAA level in control oysters for the same length of time (see Table 3). In contrast, glycine and β -alanine levels in oysters held in the high turbidity tank for 2 days increased by only a factor of 1.30 and 1.61 respectively. As shown in Tables 2 and 3, the taurine level in oysters held in the high salinity tank for 2 days increased only a factor of 1.47, whereas glycine and β -alanine levels in oysters held in this tank for the same length of time were 2.90- and 3.05-fold higher than the levels in control oysters.

Powell et al. (1982) also observed elevated FAA levels in *C. virginica* held for 2 days in a high turbidity tank containing kaolin clay as turbid particles. Particularly, the oysters held in the kaolin-clay tank showed a remarkable increase in taurine and cystic acid levels. One possible explanation for the observed increase in taurine level in the oysters in this study would be the elevated mucus secretion activities. The oysters in the high turbidity tank would secrete more mucus to remove the kaolin clay particles captured in the gills. According to Powell et al. (1982), mucus of marine invertebrates, including oysters, contains high level of sulfate anion. An increase in mucus secretion in oysters may result in cystic acid levels in the FAA pool because an increase in sulfate anion level in the mucus also elevates a precursor compound for cystic acid. Powell et al. (1982) also observed that an increase in cystic acid levels accompanies an increase of taurine levels in their study. Thus, we postulate that, in this study, the observed increased taurine levels in the oysters in the high turbidity tank on day 2 was influenced by elevated cystic acid levels in the mucus, although cystic acid was not analyzed in this study.

Oysters in hypo-osmotic conditions for 2 days exhibited slightly decreased total FAA levels in the gill tissues. As shown in Table 2, aspartic acid, taurine, and L-alanine levels in the oyster gill tissues dropped more than 30% compared with the level of control oysters. In contrast, glutamic acid and β -alanine levels in oysters in low salinity conditions were much higher than the levels observed among control oysters. Especially, the β -alanine level in the oysters was 10 times higher than the level in the control oysters, and 3–5 times higher than the level in oysters held in the high

salinity or high turbidity tanks. Although the β -alanine levels showed dramatic changes after 2 days in the tank, the role of β -alanine in the FAA pool's response to osmotic stress seems to be minor; β -alanine accounts only for 8% of the total FAA. Elevation of β -alanine levels was also observed in *C. virginica* held in increased salinity, anoxia, drilling effluent from oil drilling operations, and high turbidity treatments for 5 days (Powell et al. 1982). An increase in β -alanine levels was also reported from sea anemones raised in a laboratory and in the field (Low et al. 1980). It is likely that the elevation of β -alanine observed in *C. gigas* is a unique physiologic response to stress, although the mechanism of β -alanine elevation in the FAA pool of either *C. virginica* or *C. gigas* is not fully understood.

FAA levels in oysters in the experimental tanks at day 5 were considerably decreased compared with either the day 5 controls or the day 2 treatment groups (see Table 2). Decreases in FAA between days 2 and 5 were very conspicuous in the oysters held in the low salinity tank. All amino acids analyzed in the oysters exhibited an 8.8%–72% decrease in FAA between days 2 and 5. Specifically the levels of glutamic acid declined dramatically between those two days. Those levels dropped 53.5%, 68.5%, and 64.1% respectively in the high salinity, low salinity, and high turbidity tanks. However, it is unlikely that the dramatic changes in glutamic acid observed in this study exert a great influence on osmotic balance of the oysters since glutamic acid is a minor constituent of the FAA pool. Glutamic acid accounts for only 2.8%–5.5% of the total FAA at day 5. In contrast, taurine, which comprises from 62.6%–82.0% of the total FAA pool in the oysters at day 5, remained less changed compared with other amino acids.

A considerable decrease in FAA was also observed in *C. virginica* held in drilling effluent, anoxia, and high turbidity tanks between days 2 and 5; the oysters exhibited a remarkable decrease in FAA, including taurine, glycine, and alanine (Powell et al. 1982). Particularly, the taurine level in the oysters dropped as much as 58% in the anoxia tank between days 2 and 5. Powell et al. (1982) postulated that such a considerable drop in amino acid levels in *C. virginica* could be attributed to a general loss of FAA from the gills. This was because of some changes in the tissue's ability to prevent FAA loss across the outer membrane of the cells in the gill tissues, as indicated by another study (Bishop et al. 1994). Although the extent of decrease in the taurine level in *C. gigas* was not as great in as *C. virginica*, the oysters held in the kaolin turbidity tank, in this study, also showed a remarkable decrease in the taurine level between days 2 and 5. It is believed that *C. gigas*, in the kaolin tank, also loses a large amount of taurine through the gills, as observed in *C. virginica*.

ACKNOWLEDGMENTS

We are grateful to E. N. Powell of Haskin Shellfish Laboratory of Rutgers University and Charles Bai of Pukyong National University for reviewing and commenting on the manuscript. ABSTRACT The oyster *Ostreola conchaphila* is endemic to shallow subtidal and low intertidal marine waters of the West coast of North America. The heat shock response of the species was characterized for both adult and early life stages. *O. conchaphila* expressed proteins that were the same molecular weights as and were immunologically related to the heat shock protein (Hsp)70 family of proteins that have been described for the oyster, *Crassostrea gigas*. Hsp77 and Hsp72 were present in adult and larval tissue. Expression of Hsp69 occurred in adults that were heat shocked at 33–38 °C, regardless of season or previous environmental temperature regimen. A heat shock at 34 °C induced thermotolerance to otherwise lethal temperatures of 38.5 ° or 39 °C. Early life stage embryos (early cleavage, late cleavage, and ciliated blastula stages) were unable to express Hsp69 or mount a heat shock response. Veliger larvae expressed Hsp69 after a 34 °C heat shock. The increased Hsp69 persisted for at least 12 h after 1 h of heat shock as opposed to the acquisition of thermotolerance, which had declined by 12 h after heat shock.

KEY WORDS: Hsp70, thermotolerance, larvae, Olympia oyster, Native oyster, *Ostrea conchaphila*

INTRODUCTION

An important component of tolerance to stress at the cellular level involves the “heat shock response.” This response involves changes in the levels of several families of heat shock proteins (Hsps) or molecular chaperones that stabilize protein conformation and function in the face of denaturing stress, including thermal stress, thus providing protection (Lindquist 1986, Gething & Sambrook 1992, Morimoto et al. 1994). Typically part of the response involves selective expression of certain inducible Hsps, which in turn can provide an enhanced tolerance beyond lethal conditions (Parsell & Lindquist 1994, Mailhos et al. 1993, 1994). Three Hsp isoforms exist: two are constitutive, Hsp77 and Hsp72, and are routinely present in cells, whereas the expression of a third, Hsp69, is induced after thermal shock (Clegg et al. 1998, Feder & Hoffman 1999). The Hsp70 family is directly implicated in thermal tolerance of several marine invertebrates, however, the temperature at which the heat shock response is activated not only differs between species, but can also vary within species as a result of environmental or physiologic history. For example, the temperature for induction (set point) of the heat shock response in the intertidal mollusks within the genera *Tegula*, *Mytilus*, and *Crassostrea* is a function of acclimatization to past thermal conditions (Tomanek & Somero, 1999, Buckley et al. 2001, Hamdoun et al. 2003). And, in at least one genus, *Crassostrea*, there is a cost to this acclimation: this increase of the Hsp induction set point is not balanced by an equivalent increase in the thermal tolerance limit (Hamdoun et al. 2003). Thus, thermally acclimatized *Crassostrea* may be less fit to tolerate stress.

The North American Olympia oyster, *Ostreola conchaphila*, has been characterized as intolerant to both tidal exposure and temperature stress. A native to the coast of western North America from Sitka, Alaska to Panama (Harbo 1997), this comparatively small (<60 mm) and slow growing species is found attached to rock or other hardened substrates in bays and estuaries extending

from low intertidal to shallow subtidal depths (Baker 1995). Like other oysters of the genus *Ostrea* and *Ostreola*, fertilization and embryonic development in *O. conchaphila* take place in the mantle cavity of females, thus early life stages are captive to the same environmental conditions as brooding adults. Hopkins (1937) reported that *Ostrea lurida* (*O. conchaphila*) could not withstand temperatures outside the range of 0–30°C and this limited thermal tolerance range was described as the primary constraint to geographical distribution of the species. This upper thermal limit is considerably lower than that reported for its European congener, *Ostrea edulis* (40°C) or the Japanese oyster, *Crassostrea gigas* (43–44°C), both of which inhabit intertidal to shallow subtidal environments, but do so over a broader geographical range (Clegg et al. 1998, Piano et al. 2002).

In the present report, we characterize the heat shock response for *O. conchaphila* adults and veliger larvae from Tomales Bay, California. We present evidence for the induced expression of Hsp 69 after thermal stress, demonstrate that the response is short-lived, but does convey thermal tolerance, and discuss the ecological significance of this response. We present evidence that the response is not present in pre-gastrula embryos and appears to be more truncated in larvae than in adults. Lastly, we address the question: Is the Hsp70 family expression pattern in *O. conchaphila* genetically fixed and how does this response compare with the phenotypic plasticity observed in *C. gigas* and other marine invertebrates?

MATERIALS AND METHODS

Animal Collection and Maintenance

Adult oysters were collected from Tomales Bay, California, at a tidal height of 0–1.0 ft and transported to the Bodega Marine Laboratory within 1–2 h of collection. Animals were maintained in flow-through seawater tanks with aeration at 12–15°C and were fed an algal paste daily consisting of *Chaetoceros*, *Tetraselmis*, and *Isochrysis* (Reed Mariculture, Inc). Collections were conducted during June through July over successive years (2000 and

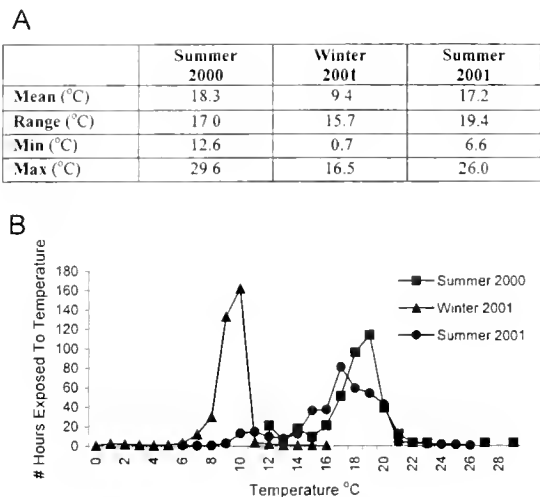

Figure 1. Temperature profile for Tomales Bay. Hobo samplers were used to collect temperatures at the tidal height and location of *O. conchaphila* for a 2-week period prior to each collection. A, Temperature range (range), mean, minimum (min), and maximum (max) temperatures were calculated for each site. B, In addition, the total number of hours at each temperature (rounded to the nearest °C) over the 2-week period was calculated.

2001), with one collection during December 2000 for seasonal comparison. Adults were used in heat shock experiments within 3–5 days of collection. During recovery periods after heat shock, adults were maintained in the flow-through seawater tanks and fed as described above.

Embryos and larvae were obtained from brooding females collected during the summer: the reproductive season in northern California extends from May to September, during which time females brood embryos for the first 10–12 days of embryonic development (Bonnot 1935, Baker 1995). To remove the larvae from females, the right valve of the shell was removed and the mantle cavity was rinsed with 0.45-µm filtered seawater (FSW) over an 85-µm mesh screen to filter out large debris. The filtrate, containing embryos or larvae was then passed through a 20-µm filter to collect and concentrate the larvae. Collected embryos or larvae were cultured in aerated FSW, 15°C, in 20 × 11 × 6-cm glass dishes at a concentration of approximately 200 embryos per

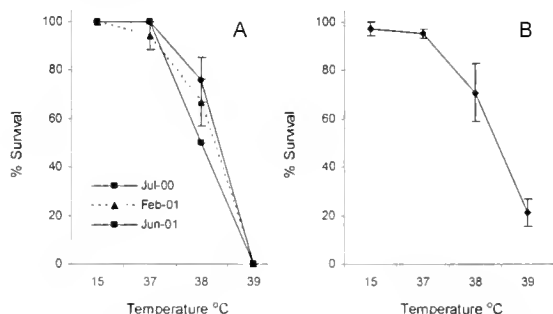

Figure 2. Lethal temperature profiles for adult and larval *O. conchaphila*. A, Survival of adults during summer 2000, winter 2001, and summer 2001 after a 1-h heat shock at 37, 38, or 39°C ($n = 18$ for each data point). There was no significant difference between seasonal survival at either 37 or 38°C ($P > 0.05$). B, Survival of veliger larvae, collected in July 2002, after a 1-h heat shock at 37, 38, or 39°C (200 larvae per ml; $n = 3$). Control adults and larvae were held at 15°C.

milliliter. All experiments with embryos and larvae were conducted within 1 day of collection during which time the larvae were cocultured with *Isochrysis* as a larval food source.

Temperature Data Logging

Tomales Bay temperature data from the oyster collection site was obtained using a Hobo© Tid-Bit temperature sampler that was placed at a tidal height of 0 ft. Temperature readings were recorded at 2-min intervals between May and September 2001.

Heat Shock and Lethal Temperature Determination

For all adult heat shock experiments, animals ($n = 10$) were removed from ambient seawater and placed for one hour into pre-heated seawater in a 2L beaker that was, in turn, placed in a Neslab RTE211 waterbath that set to within 0.1°C of the experimental temperature. Adult oysters were heat shocked at temperatures ranging in one-degree increments from 32 to 39°C. After heat shock, adults were transferred back to ambient seawater, with daily feeding, to recover. Mortality was monitored daily for two weeks

Embryo and larval heat shock experiments were conducted at a concentration of 200 embryos/ml in 20-mL scintillation vials by suspending the vials in the Neslab RTE211 water bath for one hour at the appropriate temperature. Four stages of development, early cleavage, late cleavage, ciliated blastula, and veliger larvae were used in the embryo/larval heat shock experiments. Embryos and larvae were provided a 24 h post-heat shock recovery period (monitored at 4 h, 12 h, and 24 h) at 15°C, then percent mortality was scored using a dissecting microscope. The criteria for viability vs mortality was stage dependent: early cleavage embryos were considered alive if cleavage had continued post-heat shock, while motility was used as the criteria for viability in embryos/larvae in the other three stages.

Hsp70 Determinations

The presence and quantities of Hsp70 proteins were determined by using oyster proteins separated by sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) with an Hsp70 monoclonal antibody. All procedures for sampling tissue and preparation for Hsp analyses were conducted according to Clegg et al. (1998) with modifications after Hamdoun et al. (2003). Briefly, gill samples were excised 48 h postheat shock, weighed, frozen in liquid nitrogen, and stored at -80°C. For electrophoresis, the pre-weighed gill tissue was placed in potassium gluconate buffer (KGB: 5 mM MgSO₄, 5 mM NaH₂PO₄, 40 mM Hepes, 70 mM gluconic acid, 150 mM sorbitol, pH 7.5) at a concentration of 100 mg wet tissue per 1 ml of KGB. Samples were then homogenized and diluted 1:1 with 2X SDS-PAGE sample buffer and heated to 100°C for 5 min. Volumes of solubilized gill were adjusted so that equivalent gill weights for each sample were loaded onto a 10% polyacrylamide gel. The proteins separated by SDS-PAGE, and protein bands subsequently transferred to nitrocellulose. Note: gels were electrophoresed for 30 min after the tracking dye had mi-

Figure 3. Immunoblots of Hsp70 protein profiles of control (15°C) and heat shocked *O. conchaphila* adults at 1 and 24 h post-heat shock (heat shock of 1 h at 34°C).

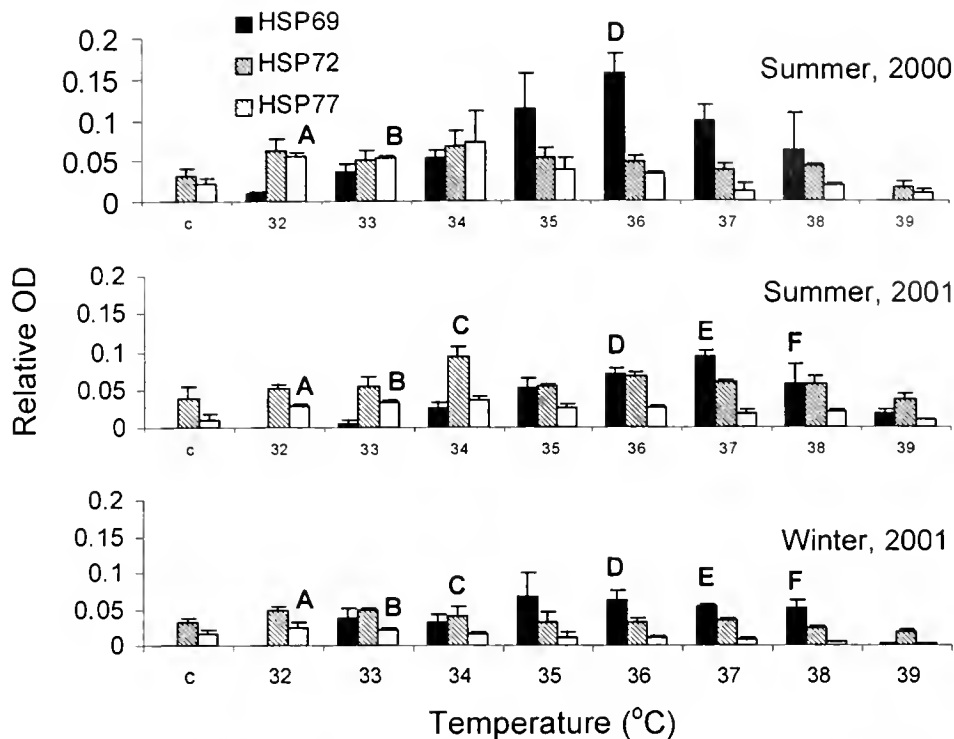

Figure 4. Hsp70 protein profiles of adult oysters after heat shock at 32–39°C. Relative levels of Hsp69 were assayed at 48 h post-heat shock in collected Summer 2000, Winter 2001 and Summer 2001. Seasonal profiles of Hsp69, 72, and 77 levels after heat shocks revealed no significant summer/winter differences (values are means \pm SEM ($n = 3$)). There were random significant differences (A-A, B-B, etc $P < 0.05$) that did not follow seasonal trends. Values were pooled and averaged \pm SEM ($n = 9$). Hsp69 levels after heat shock at temperatures ranging from 33–38°C (*) were significantly greater ($P < 0.05$) than 15°C controls or heat shock at either 32 or 39°C. Values in the seasonal data (inset) are means \pm SEM ($n = 3$ for each data set).

grated to the bottom of the gel; this provided separation of the Hsp70 isomers. Western blots were probed with a rat anti-HSP70 monoclonal antibody (MA3-001, Affinity Bioreagents) followed by a goat anti-rat horseradish peroxidase-conjugated secondary antibody (Sigma). Labeled proteins were detected using chemiluminescence (ECL, Pierce) in a UVP Epi Chemi II darkroom. Densitometry of the bands on western blots was conducted using Laboratory Works image acquisition and analysis software (UVP Bio-imaging Systems).

Larvae were sampled by removing 15–100 mg wet weight per time point from the culture vial and were concentrated on a 50- μ m nitex mesh screens. The larvae were washed with FSW, pelleted, frozen in liquid nitrogen, and stored at -80°C until all samples were collected. Prior to SDS-PAGE analysis, the larval pellets were resuspended in hypotonic lysis buffer (HLB: 10 mM KCl, 1.5 mM MgCl_2 , 10 mM Tris-HCl, pH 7.4) with protease inhibitors to 200 mg/mL, sonicated and then diluted 1:1 with 2X SDS-PAGE sample buffer and analyzed as stated above for the adults.

INDUCED THERMOTOLERANCE

Induced thermotolerance experiments followed procedures outlined in Clegg et al. (1998) with adjustments for species temperature tolerance differences. Adults received a sublethal heat shock (34°C , 1 h) and were allowed to recover at ambient for 24 h prior to a 1-h incubation at the preheat shock lethal temperature (38.5 or 39°C). Veliger larvae were subjected to a sublethal heat shock (34°C , 1 h) and subsequently incubated at the pre-heat shock lethal temperature (39°C) at 6, 8, or 12 h postslethal heat shock. Con-

trols for both adults and larvae were exposed to 38.5 or 39°C without a prior sublethal heat shock treatment. Survival of adults was assessed over a 3-wk period and larvae survival was monitored over a 24 h period.

Data Analysis

Protein levels were analyzed for statistical significance using one-way analysis of variance (Sigmastat software v2.03).

RESULTS

Collection-Site Temperature Profiles

The temperature profiles at oyster collection sites in Tomales Bay for the 2 weeks leading up to each sampling are summarized in Figure 1. The profiles differed not only between winter and summer but also slightly between the two summer sampling periods. During the winter sampling, temperatures ranged from 0.7 to 16.5°C ; however, greater than 90% of the degree-hours (the number of hours at a particular temperature) for the 2-week period fell within a 3-degree range, 8 – 10°C (Fig. 1). During the summer there was more variation in water temperature; the ranges were 12.6 – 29.6°C and 6.6 – 26.0°C for 2000 and 2001, respectively. The temperature ranges that encompassed 90% of the degree hours for the 2-week summer periods were also broader, 16 – 20°C and 14 – 20°C , respectively.

Lethal Temperature Determination

The lethal temperature for *O. conchaphila* adult and larval life stages is between 38°C and 39°C . No adult oysters survived heat

shock for 1 h at 39°C, and the range of survival subsequent to a 1 h exposure to 38°C was 50–87%, with no statistically significant seasonal difference ($P > 0.1$; Figure 2A). Brooded veliger larvae (from summer collections) mimicked the adult pattern: 70.7 \pm 12.01% SD (range of 59–83%) of larvae survived a heat shock of 38°C while only 21.3 \pm 5.7% SD (range of 15–26%) survived 39°C (Fig. 2B).

Adult Hsp Protein Profiles

Ostrea conchaphila expresses the Hsp70 family of heat shock proteins: constitutive (Hsp77 and Hsp72) and inducible (Hsp69) forms co-migrated with and were immunologically similar to the Hsp isomers described for *C. gigas* and *O. edulis* (Fig. 3; Clegg et al. 1998, Piano et al. 2002). Oysters maintained in ambient sea-water (15°C) and individuals that were assayed 60 min after heat shock (60 min at 34°C) were indistinguishable in Hsp70 profiles. Both possessed Hsp72 and Hsp77 (Fig. 3). By 24 h post-heat shock, however, the inducible isoform, Hsp69, as well as the two constitutive Hsp70s, were present (Fig. 3). The lowest heat-shock temperature at which Hsp69 was consistently induced (T_{on}) was 34°C regardless of season, whereas the highest heat-shock temperature (T_{off}) at which Hsp69 was consistently seen was 38°C (39°C was the lethal temperature), also regardless of season (Fig. 4). Hsp69 was maximal (assayed at 48 h post-heat shock) when the heat shock temperature was between 35 and 38°C during the summer and 32–38°C during the winter, but there was no significant difference in the level of Hsp69 expression for specific heat shock temperatures between seasons (Fig. 4). Likewise, the overall levels of the constitutive forms, Hsp72 and Hsp77, did not follow seasonal patterns, nor did they change significantly as a result of heat shock.

Once induced, Hsp69 remained present in adults for at least 3 days, but was maximal at the 24 and 48 h post-heat shock sampling times (Fig. 5). Quantities of Hsp69 were statistically indistinguishable at 24 and 48 h within all seasonal samples, and were significantly reduced by day 3 in two of the collections, summer, 2000 and winter, 2001. In all collections there was a significant decline in Hsp69 from 24–48 h post-heat shock levels to the 3–7 day levels ($P < 0.05$; Fig. 5). And, although not statistically significant, this declining trend was evident between 24 and 48 h and between 3 and 7 days in all collections (Fig. 5).

Long-Term Survival of Adults After Induced Thermotolerance

Heat shock did induce thermotolerance in *O. conchaphila* but only over a narrow time span. Initial experiments showed that tolerance to the naïve lethal temperature of 39°C was present at 24 h post-sublethal heat shock but not at 48 h. None of the oysters that were heat shocked at 34°C and then exposed to 39°C at 48 h post-heat shock survived a week, whereas 100% that were exposed to 39°C at 24 h post-heat shock, survived. Hsp69 levels did not reflect the decline in acquired thermal tolerance; at 24 and 48 h Hsp69 levels were not significantly different ($P > 0.05$; see Fig. 5). Only in one collection (summer 2000) was there a significant difference between Hsp69 levels at 3 days post-heat shock (Fig. 5). Because the duration of induced thermal tolerance was much shorter than that reported for other oysters (Clegg et al. 1998), we investigated whether long-term survival was compromised by post heat-shock exposure to lethal temperatures. Animals that were exposed to 38.5 or 39°C at 24 h after a 34°C sublethal heat-shock exhibited temperature dependent survival. Pre-heat shock animals that were placed directly from 12°C into lethal temperature sea-

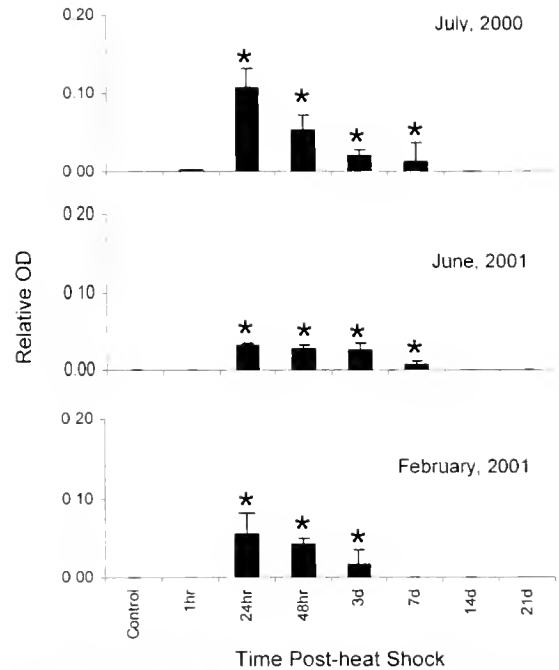

Figure 5. Hsp69 levels as a function of time (hours & days) post-heat shock. Relative levels of Hsp69 were assayed for up to 21 days after a 34°C heat shock of adult oysters collected during summer 2000, winter 2001, and summer 2001. Levels of post-heat shock Hsp69 were significantly different than 15°C controls ($*P < 0.05$) at 24 h, 48 h, and 3 days post-heat shock for all three collections. The only between season significant obtained was that Hsp69 was present through 7 days post-heat shock for the summer, but not winter collections.

water, 38.5 or 39°C, died also in a temperature dependent manner over the course of the experiment. All naïve adults that were exposed to 39°C died within 6 days while those exposed to 38.5°C perished over the course of 20 days, 36.7 \pm 19.6% (SE) survived 10 days and 20.7 \pm 10.4% survived to 20 days (Fig. 6A). In contrast, all of the adults that were heat shocked at 34°C prior to 38.5 or 39°C exposure at 24 h post-heat shock, survived 6 days (Fig. 6B). After 20 days 88.7 \pm 5.7% of adults subjected to 38.5°C and 66.7 \pm 9.5% of those exposed to 39°C survived, significantly higher survival than in the nonheat shock groups ($P < 0.05$, Fig. 6). Survival of the oysters exposed to the 38.5°C lethal temperature post-heat shock was significantly higher than that of the 39°C group after 20 days ($P < 0.05$).

Larval Heat Shock Response

All four developmental stages, early cleavage, late cleavage, blastula, and prerelease veliger larva, contained constitutive Hsp77 and Hsp72; however, only the veliger larval stage possessed Hsp69 after heat shock (Fig. 7). Hsp69 was present in veliger larvae by 6 h post-heat shock and had increased by a factor of four at 12 h post-heat shock (Fig. 8). In contrast to the temporal increase in Hsp69 over the first 12 h post-heat shock, thermotolerance decreased (Fig. 9). Heat shocked larvae were more tolerant to a 39°C post-heat shock treatment at 6 h after heat shock than at 12 h post-heat shock.

DISCUSSION

The preheat shock and post-heat shock thermal tolerance profiles of Hsp70 isoforms in *O. conchaphila* adults are similar to that

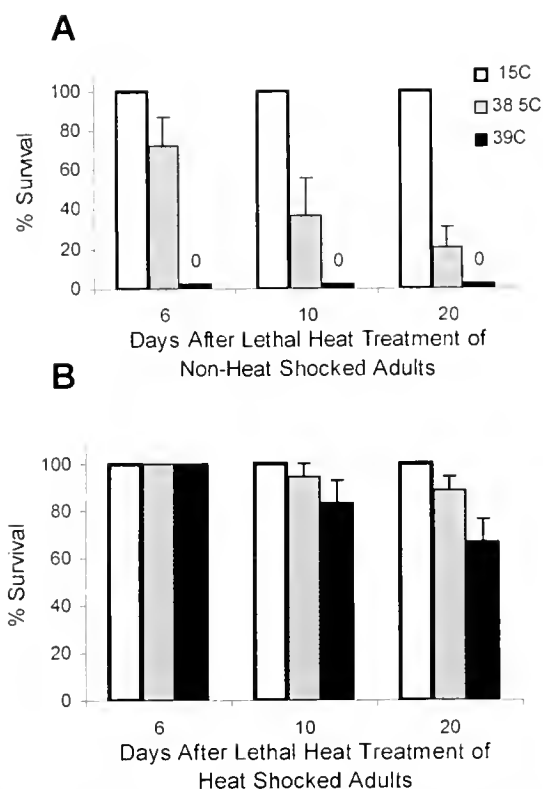

Figure 6. Long-term survival of adult oysters after sublethal heat shock followed by a lethal temperature exposure. **A.** Animals were heat shocked at the naïve lethal temperature of 38.5 or 39°C (ITT 38.5 and ITT 39). Survival was assessed at days 6, 10, and 20. Control animals were kept at ambient (15°C) temperature. **B.** Animals were heat shocked at the sublethal 34°C and after 24 h at ambient, heat shocked at a naïve lethal temperature of 38.5 or 39°C (ITT 38.5 and ITT 39). Control animals were kept in ambient (15°C) temperature following sublethal heat shock. Survival was assessed at days 6, 10, and 20 postlethal heat treatment ($n = 3$ replicates of 6 animals at each condition with each data point \pm SEM).

reported for a closely related oyster, *Ostrea edulis*, (see Pirano et al. 2002). Adults of *O. conchaphila* exhibited a pre-heat shock thermal limit between 38 and 39°C, whereas the thermal ceiling in *O. edulis*, was between 39 and 40°C (Pirano et al. 2002). Both species initiate expression of inducible Hsp69 at 32–33°C, and express Hsp69 maximally at 24–48 h post heat shock (Figs. 2 and 5; Pirano et al. 2002). In the present study we have shown that exposure of *O. conchaphila*, to a sublethal temperature high enough to induce Hsp69 expression also induces tolerance to the pre-heat shock lethal temperature of 39°C that lasts for 24 h. This induced thermal tolerance is not as dramatic as that seen in either *Crassostrea* or *Mytilus* species and, in part, explain the comparatively restricted geographical and bathymetric distribution of *O. conchaphila* (Hopkins 1937).

Research into the heat shock response of intertidal molluscs supports the concept of thermal plasticity. Both *Crassostrea* and *Tegula* modulate temperature tolerance ranges and thresholds of Hsp production based on acclimation to changes in environmental conditions such as seasonal temperature shifts or tidal height exposure (Roberts et al. 1997, Tomanek & Somero 1999, Buckley et al. 2001, Hamdoun et al. 2002). Hamdoun et al. (2003) demonstrated that seasonal increases in ambient temperature led to elevated levels of constitutive Hsps (Hsp77 and Hsp72), and to

Figure 7. Hsp70 profiles of four different early life stages of *O. conchaphila*. EC, early cleavage; LC, late cleavage; CB, ciliated blastula; VEL, veliger larva. The four stages were heat shocked for 1 h at 31 or 34°C, after which samples were assayed for the presence of Hsp70 proteins. Only the veliger larva possessed Hsp69 and did so only after heat shock at 34°C.

seasonal increases (2–3 degrees) in pre-heat shock thermal tolerance. Thus, *C. gigas* is capable of adjusting its thermal response to accommodate baseline environmental conditions. *Ostreola conchaphila* did not exhibit a significant seasonal change in constitutive Hsp levels, nor was there a shift in Hsp69 T_{on} or change in the upper thermal tolerance limit although the mean summer temperature was twice that of the mean winter temperature (18.3 and 17.3°C vs 9.4°C). It appears that *O. conchaphila*, does not possess the capability of adapting to seasonal temperature shifts that is

Figure 8. Detection of larval Hsp69 after heat shock. Veliger larvae were heat shocked at 34°C and assayed for the presence of Hsp69 at 6, 8, and 12 h post-heat shock

Figure 9. Duration of induced thermal tolerance in veliger larvae. Veliger larvae were heat shocked at 34°C and subsequently given a second thermal shock at 39°C (a lethal temperature to naïve larvae) at 6, 8, or 12 h post-heat shock. Mortality was assessed at 1 h later. Larvae at both 8 and 12 h post-heat shock (A*) had significantly higher mortality ($P < 0.05$) after a lethal heat shock than did non-heat shocked controls or 6 h post-shock larvae (A).

exhibited by other intertidal bivalves examined to date (Tomanek & Somero, 1999; Buckley et al. 2001; Hamdoun et al. 2003), reinforcing the idea that the distribution of *Ostreola* is primarily temperature determined.

Ostrea conchaphila are protandic hermaphrodites that exhibit a larviparous form of reproduction. Embryonic and early larval stages are brooded within the mantle cavity of female stage adults during the late spring and early summer, after which larvae are released as planktotrophic veligers (Santos 1992). Developmental stages are thus captive to temperature conditions experienced by brooding adults, temperatures that can approach adult lethal limits (Korringa 1976b). The fact that the lethal temperature for early life stages of *O. conchaphila* is the same as that for adults (38.5–39°C) may be an adaptation to survive captive (brooded) developmental periods. Typically early life stages are less tolerant of environmental stresses than is the adult life stage. Our results show that embryonic stages prior to gastrulation (early cleavage, late cleavage, ciliated blastula) were not able to mount a heat shock response, but

that the veliger larvae were able to do so. This developmental stage discrepancy to mount a heat shock response indicates that the embryonic genome is not transcriptionally active during early developmental stages and that maternal message for Hsp69 is not present as has been described for other species (e. g sea urchin; for a review see Giudice et al. 1999).

Interesting differences were observed between induced thermal tolerance and the presence of Hsp69 in veliger larvae that did not parallel tolerance and Hsp69 patterns seen in adults. While the quantity of Hsp69 in veliger larvae increased for the first 12 h post-heat shock, the ability to survive the naïve lethal temperature (39°C) after heat shock declined between 6 and 12 h. This could be explained by either a disconnect between the presence of Hsp69 and thermal tolerance in veliger larvae or by a general decline in condition, not necessarily heat shock associated, that lessens a larvae's ability to withstand stress. Larvae that are pre-maturely removed from brooding females, as was the case in the present study, typically do not survive to settlement (unpublished observations). Thus, young veliger larvae appear to require the environment of the mantle cavity; seawater is not sufficient for development until larvae have matured sufficient for natural release. Whether differences in the relationship between Hsp69 levels and thermal tolerance observed between adults and veliger larvae represent inherent life stage-specific physiologic states or are related to early removal of larvae from the mantle cavity is not known. To delineate which is operative, the heat shock response of brooded larvae for which the parent has been heat shocked prior to larval release needs to be investigated. Regardless of the duration of the heat shock response and relationship to Hsp69 levels, larvae that possess Hsp69 do produce a heat shock response that is within the same tolerance range as adults.

ACKNOWLEDGMENTS

The authors thank Karl Menard (Bodega Marine Lab) and Eric Larson (California Department of Fish and Game) for aid in obtaining adult *O. conchaphila*. The research was supported by the City of San Francisco. The authors also acknowledge the "Environmental Stress and Development in Marine Organisms" Summer Course at Bodega Marine Lab (ETX/NUT 127) for providing the support and the opportunity for A.M. Briden and T. Stokell to conduct portions of this research.

CORRELATION OF ODOR AND COLOR PROFILES OF OYSTERS (*CRASSOSTREA VIRGINICA*) WITH ELECTRONIC NOSE AND COLOR MACHINE VISION

ÖZLEM TOKUŞOĞLU^{1*} AND MURAT Ö. BALABAN²

¹Ege University, Engineering Faculty, Department of Food Engineering, 35100, Bornova, Izmir, Turkey;

²University of Florida, Food Science and Human Nutrition Department, Gainesville, FL, USA 32611

ABSTRACT Odor and color changes in oysters (*Crassostrea virginica*) stored at 1.8 and 7 °C were measured every 3 days for up to 13 days with an electronic nose, a computer vision system, and sensory panels. Electronic nose and odor sensory data was analyzed using Discriminant Function Analysis (DFA). Correct classification rates of 100% were obtained to group electronic nose data by days and sensory scores at each temperature. When all temperature and days data were pooled, DFA predicted sensory scores based on electronic nose readings with 94% accuracy. Oyster colors were analyzed using the 512 color block scheme. Eight colors were found to be significant. The correlations of these colors, as well as the average L*a*b* values with time and with color sensory data suggested prediction of color quality. This study suggests that electronic nose and color vision could be used to objectively evaluate the quality of oysters.

KEY WORDS: oyster, E-Nose, machine vision, odor and visual quality

INTRODUCTION

Oysters are a valuable commodity worldwide. In 1998, United States' domestic landings of oysters by weight of meat was 15,213 metric tons, valued at \$88 million (U.S. Department of Commerce, 1999). Imports increased from 4,506 metric tons in 1997 to 6,169 metric tons, valued at \$25 million, in 1998.

Oysters have a distinctive odor and flavor. Fresh shellfish products indicates typical aquatic fresh odor, brilliant appearance and physical peculiarities of the species in good situation (Perkins et al. 1992). The odor of seafood has been widely used as one of the signs of quality for a long time (Botta et al. 1995), the flesh color is a measure of the freshness of the seafood and research proves that consumers equate freshness with the vibrancy of the flesh color (Beaudoin, 1997).

Most studies regarding shellfish quality have focused on taste-active and flavor components (Sekiwa et al., 1997; Ok et al., 1996; Lee et al., 1995; Tanchotikul and Hsieh, 1991). Effects of chemical and other treatments on the taste and color of shellfish were also studied (Jawahar et al., 1994; Chellappan, 1991).

Fresh shellfish products should be marketed as fast as possible since their shelf life is very short. A critical commercial step after sorting is the inspection of the product. Current techniques concerning the quality assessments of oysters rely on sensory inspections that use the senses of vision, smell, etc. These are difficult to quantify to compare with objective standards and their results are not sufficiently repeatable. There is a necessity for objective, more reliable and quick technique to evaluate the quality of shucked oyster, to serve for these sector and international markets.

Developments in sensor technology and electronic noses (EN) have many potential applications in the food industry (Bartlett et al., 1997; Corcoran et al., 1993) including flavor and aroma profiles fresh squeezed orange juice, coffee powder, beer and cheese (Bazemore et al., 1996; Delaure et al., 1996; Pearce et al., 1993; Jou and Harper, 1998), quality control area of grapes, olive oil, ground beef, (Tokuşoğlu and Balaban, 2000; Aparicio et al., 2000; Winquist et al., 1993), aroma discrimination of black teas (Tokuşoğlu et al. 2002; Tokuşoğlu, 2001), separation of spice and grain mixture (Brezmes et al., 1997; Borjesson et al., 1996),

among others. Some work was published on the correlation of EN sensor outputs with sensory data in seafood products. EN has been applied to odor evaluation of seafood (Dodd et al., 2000; Luzuriaga, 1999; Balaban et al., 1996; Balaban et al., 1994).

Computer vision is being used in some food and agricultural areas to automate the inspection of visual quality (Sarkar et al., 1991). Visual inspection of seafood products involves image processing software and video cameras to evaluate product color, appearance, size or shape. There is reported research in the application of the machine vision technology for quality evaluation of seafood (Balaban et al., 1994; Balaban et al., 1996; Luzuriaga et al., 1995; Luzuriaga et al., 1997; Newman et al., 1998), for grading and sorting (Par et al., 1995; Diehl et al., 1990) and for shape detection (So et al., 1996). No study could be found concerning quality determination of oysters with E-nose and computer vision for objective evaluation. The objectives of this study were 1) to develop predictive models of odor change in shucked oysters stored at 1.8, and 7 °C using an electronic nose, 2) to correlate these readings with sensory evaluation data, 3) to develop models of color change in these samples using machine vision and correlate them with visual sensory evaluation data.

MATERIALS AND METHODS

Oyster Samples and Storage Conditions

Fresh oysters (*Crassostrea virginica*) from Apalachicola, FL in the Gulf of Mexico were obtained. The weight of each oyster with the shell was approximately 75 g; the meat was approximately 20% of the total weight, about 15 g. Dating from the first day, they were stored in 100 ml beakers, 2 oysters per covered beaker, in cold rooms at 1.8, and 7.0°C for up to 13 days. For the machine vision experiments, 2 oysters were placed in a small petri dish (60 mm diameter), the lids covered, and stored at the same temperatures. The samples were analyzed every three days. This study was repeated twice.

Electronic Nose Measurements

An Electronic Nose model 4000 (EEV Inc, UK) equipped with 12 conducting polymer sensors (types 458, 459, 460, 461, 462,

*Corresponding author. E-mail: otokusoglu@superonline.com

463, 464, 478, 483, 297, 298, 401) was used. Before the experiment started, E-nose was calibrated with propylene glycol (chromatographic grade, Fischer Scientific, No. P-355-20, Fair Lawn, NJ; 75% v/v) as recommended by the manufacturer.

Every day before the experiments, compressed dry air (CGA Grade D, Strade Welding Supply Inc., Jacksonville, FL) was passed through the EN sensors for 20 min. A covered beaker containing oyster samples was taken out of the cold room one hour before analysis and equilibrated to room temperature (25 °C). The beaker was then placed in the EN. Five consecutive readings were taken for each sample. Then, the replicate sample was taken out of the cold room and treated similarly. For each reading, the vessel and head were purged with dry air for 2 and 4 min, respectively. Then, sensor responses were read for 4 min. For each sample total analysis time was 10 min.

Computer Vision Analysis

The color machine vision system developed by Luzuriaga and Balaban (1997) was used to grab images. The light box had 3 sections consisting of a top lighting box, a bottom lighting box and a sample chamber. The illuminant was 15 watt Chroma 50 fluorescent light (F15T8-C50, General Electric, Cleveland, OH). The S-video output of a video camera (Sony SSC-S20, Sony Corp., Japan) was connected to a color frame grabber (Meteor, Matrox Electronic Systems, Ltd., Dorval, Quebec) mounted inside a Pentium 133 MHz PC computer. In this experiment, the settings for the video camera were: hue = 0, saturation = 160, contrast = 160, and brightness = 148 (for a range from 0 to 255). During image acquisition a standard color tile (beige, L = 63.59, a = 65.19, b = 33.39) was placed next to the oyster samples in the light box.

For each sampling day, the small petri dish was removed from the cold room, placed in the light box with front and back lighting, the image of oysters stored 1.8 and 7.0 °C was captured and saved in a computer file. The petri dish was then placed back in the cold room. The same samples were used throughout the experiment. This study was repeated twice. Oysters remained at room temperature for no more than about 5 min during image capture.

Images were calibrated by the color analysis software using the standard color tile (Luzuriaga, 1999). The color of the calibrated images was reported in the RGB and L, a, b color systems. The 512-color blocks scheme was used for the RGB colors (Luzuriaga, 1999). The value for each color block was the percent of the view area of the oyster covered by that color. Colors that were more than 5% of the total area were considered.

Sensory Evaluation

The odor and color of oyster samples were analyzed by a 10-member trained sensory panel consisting of graduate students, professors, and personal, 24-50 y of age, from the Food Science and Human Nutrition Dept. at the University of Florida. Panelists were trained using oyster samples from the same supplier utilizing a descriptive sensory analysis method. They used the samples as "excellent" and "poor" as a guide in their decision to evaluate odor and color for the unknown samples, respectively. Samples stored at two different temperatures were evaluated using odor description for the best sample; typical aquatic fresh odor, distinctive oyster aroma, and the worst sample; deteriorated odor, putrefactive aroma. For color description the best sample had brilliant color,

Figure 1. DFA of oyster odor based on sensory criteria from both temperatures pooled together and EN readings (Ellipses = 90% confidence area).

good appearance, and the worst sample had deteriorated, dull, slimy appearance.

A 5-point scale was used in this study where 1 = poor, 2 = fair, 3 = good, 4 = very good, 5 = excellent. Samples were evaluated for odor and color every three day for up to 13 days. This study was applied according to IFT Sensory Evaluation Division (IFT, 1994). Odor and color profile in descriptive sensory profiling was applied as a method (Piggott et al., 1998) and hedonic scale was carried out as an overall acceptability test in consumer and acceptance tests.

Data Analysis

Discriminant Function Analysis (DFA), a parametric procedure to identify relationships between qualitative variables such as sensory descriptors, odor, color classes, and quantitative variables such as sensor response, was used. It tries to classify samples into known groups by constructing linear relationships for the sensor data or color data and the criterion set of variables. This method generates functions that are used to classify samples. Each discriminant function is calculated for which the F-ratio of the analysis of the variance is maximized (Gardner and Hines, 1997).

$$\text{Function } F_1 = \sum_{j=1}^{12} a_{1j} x_{1j} + a_1 \quad (1)$$

Function 1 gives the most separation between groups, function

2 gives the next best separation, and so on. Generally the first two functions are sufficient to separate the groups. E-nose sensor readings, color vision data and sensory scores were analyzed in Statistica for Windows ('98 edition, Ver. 6.0, StatSoft Inc., Tulsa, OK) using discriminant function analysis (DFA) to develop the predictive functions for oysters stored at different temperatures and storage times, and to correlate these with sensory data.

In this study, the 12 sensor outputs in E-nose analysis and 8 color outputs obtained from color analysis were reduced to 2 discriminant functions. These functions were used to graph the data in two dimensional plots and observe separation of groups. For each function, coefficients and correct classification matrix were obtained.

RESULTS AND DISCUSSION

E-nose readings with odor sensory evaluation data for oyster stored at different temperatures for different times were correlated and also machine vision readings with color sensory evaluations for oyster stored at two different temperature for up to 13 days were correlated using Discriminant Function Analysis. Figure 1 indicates DFA correlations of EN readings with sensory criteria data at two storage temperature. For 1.8 and 7.0 °C, all temperature

and days pooled data, discriminant function analysis perfectly separated the E-nose data with correct classification rates of 100%, 100%, 94% respectively (Table 4).

There was no significant difference between the number of EN readings (n) used to obtain the discriminant functions ($P < 0.01$).

During sensory panel, panelists judged the differences in odors at two different temperature for up to 13 days (Table 2). Table 2 indicates odor sensory scores of oysters stored at 1.8 and 7.0 °C by

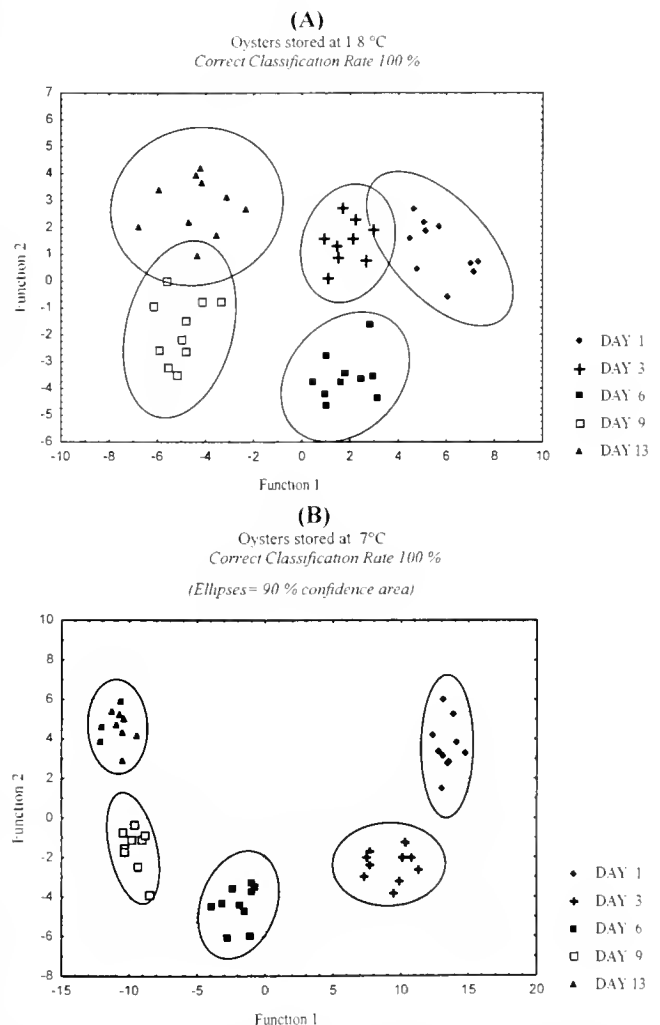

Figure 2. DFA of oyster odor based on storage time and EN readings.

sensory panel. Oyster odor changed with storage time. The differences between the two replicate of sensory scores of both temperatures were not significant ($P < 0.01$).

At two temperatures, some panelists could evaluate odor differences with difficulty between successive days while EN detected these differences clearly. After Day 3, panelists could not discriminate odor of semideteriorated and deteriorated oyster samples and these were evaluated as putrefactive aroma. When all temperature and days data were pooled together, DFA predicted sensory scores based on electronic nose readings with 94% accuracy.

DFA was used to calculate two discriminant functions to correlate EN readings with storage time at both temperature. Table 3 shows coefficients for Discriminant Functions to estimate oyster odor based on storage times at 1.8 °C, 7.0 °C and both temperatures with EN.

at 1.8, 7.0 °C gave correct classification rates of 100% and 100%, respectively (Table 4). There was no differences between the number of Electronic Nose readings (n) used to obtain the discriminant functions ($P < 0.01$). Figure 2 shows a clear discrimination for up to 13 days at both temperature. As shown in these figures, there was no overlap in days, meaning that there were definite differences in the sensor readings for each day of storage.

Computer vision could clearly quantify non-uniform colors of oyster. Classification functions of the correlation between color data and storage time, as well as color sensory evaluation data, were obtained. When classified by day at each temperature, the classification rates for 1.8 °C and 7.0 °C were 100% and 100%, respectively. Classification of color data by sensory readings gave classification rate of 100%, 100%, respectively.

Eight colors were found to be significant for oyster color quality with RGB color system. The correlations of these colors, as well as the average L*a*b* values with time and with color sensory data suggested prediction of color quality.

Figure 3 shows average L*a*b* values of oysters stored at 1.8 °C. The lightness scale (L) differences of oyster samples for both replicates were not significant ($p < 0.01$). Redness or greenness (a) and yellowness or blueness (b) can reflect a single color function called color difference, and this difference is a measure of the distance in color space between two colors. According to L*a*b* results, the differences of oyster color stored for up to 13 days could not be clearly determined (Fig. 3).

The panelists judged differences in color quality in both temperatures during storage time and in the same samples evaluated for up to 13 days (Table 5). Table 5 indicates color sensory scores of oysters stored at 1.8 °C and 7 °C by the sensory panel. Oyster color changed with storage time. The differences between the two replicates of sensory scores of both temperatures were not significant ($p < 0.01$).

At 1.8 °C and 7.0 °C, panelists could not evaluate color quality differences after day 3, whereas machine vision clearly determined these differences between semideteriorated and dull, slimy samples.

Each color block of oyster and RGB values of these colors were determined using the color machine vision system and the eight colors obtained are shown in Table 6.

Six of the 8 colors were identified as deteriorated color whereas the remaining two were represented by yellow and orange hues.

During storage time, good color, or Color 73 (RGB = 245,241,273), was decreased over time, and fresh oyster appearance was decreased as show in Fig. 4(a). The level of this color

RGB Values of Each Color Block of Oyster.

COLOR NO	R value	G value	B value	COLOR
72	48	48	16	Dark olive
73	245	241	173	Pale orange yellow
137	67	107	68	Dark yellowish green
145	80	80	48	Greyish olive
146	80	80	80	Dark grey
209	112	80	48	Moderate brown
210	112	80	80	Dark red
218	112	112	80	Greyish olive

was decreased to around 17% for storage at 1.8°C and 8% for 7.0°C from around 29%. [Fig. 4(a)]. There were no significant differences between the two replicates of color analysis ($p < 0.01$). While computer vision was determined deterioration from after day 3, objectively; sensory criteria could not evaluate visual quality of oysters. Color (145 + 146) (RGB = 80,80,64) increased over time and level of this color was increased to around 27% for storage at 1.8°C and 36% for 7.0°C from around 16%, respectively [Fig. 4(b)]. These additional colors were responsible for the grayish-dark blue of deteriorated oyster.

E-nose and machine vision data can be used in pattern recognition for objective classification of oyster. With comprehensive study oyster samples by odor and color, the e-nose can be used reliably to classify and machine vision can objectively classify oyster samples by color.

DFA can be used satisfactorily as a pattern recognition analysis technique in food engineering area for the identification and determination of seafood odor and color.

INTRASPECIFIC LIFE HISTORY VARIATION IN THE SOUTHERN OYSTER DRILL, *STRAMONITA HAEMASTOMA*: PATTERNS AND CAUSES

KENNETH M. BROWN,*¹ MICHAEL MCDONOUGH AND TERRY D. RICHARDSON

Department of Biological Sciences, Louisiana State University, Baton Rouge, Louisiana 70803;

Department of Biology, University of North Alabama, Florence, Alabama 35632

ABSTRACT Along the Louisiana coast of the Gulf of Mexico, the southern oyster drill, *Stramonita haemastoma* (Gray), reached peak densities at an exposed, coastal location, with lower but more constant densities in an estuarine oyster reef. Average oyster drill size in field samples was largest at the estuarine, intertidal reef and smallest at the exposed location. Caged oyster drills grew more rapidly and were more fecund at the subtidal, estuarine oyster reef than at the exposed location, resulting in higher biomass and production estimates. Life histories thus changed from slower growth, and delayed and semelparous reproduction at the exposed location to rapid growth, and earlier and iteroparous reproduction at the subtidal, estuarine oyster reef. When oysters were added to cages at the exposed location (where they are rare), oyster drill growth and reproductive rates increased dramatically. Trapping revealed no obvious differences in the abundances of crab predators between the estuarine and exposed site, nor were there any differences in gastropod shell thickness (e.g., vulnerability to predators). We conclude that the availability of profitable prey like oysters plays a greater role in explaining oyster drill life history variation than predation risk, and that wave exposure has only indirect effects, by limiting the availability of oysters or forcing oyster drills to feed on smaller prey.

KEY WORDS: environmental causes, life history, oyster drill, population ecology, *Stramonita haemastoma*

INTRODUCTION

The southern oyster drill, *Stramonita* (= *Thais*, Kool 1987) *haemastoma* Gray, an important predator of oysters (Brown & Richardson 1987), is common throughout the Gulf of Mexico (Butler 1985). Along with the black drum (*Pogonias cromis*), it restricts the distributions of oysters in the Gulf of Mexico to estuarine areas where salinities are too low for most predators (Chantry et al. 1983, Wilber 1992), or to the high intertidal at coastal locations (Bahr & Lanier 1981, Brown 1997, Brown & Stickle 2002, Roegner & Mann 1995). Recent research on oyster drills has concentrated on tolerance and capacity adaptations to salinity, temperature, and hypoxia (Brown & Stickle 2002, Stickle 1985, Stickle 1999), population structure (Liu et al. 1991), and foraging behavior (Brown 1997, Brown & Alexander 1994, Brown & Richardson 1987, Richardson & Brown 1990, Richardson & Brown 1992). Relatively little is known, however, about intraspecific variation in oyster drill life history characters such as growth or fecundity.

This study documents variation in density, growth, and reproduction between oyster drill populations in coastal and estuarine locations, and at a smaller scale, between an intertidal and a nearby subtidal oyster reef at the estuarine location. Contrasting coastal and estuarine sites is important because the lowered levels of wave activity (Richardson & Brown 1990) and salinity (Stickle 1985) at estuarine sites alter oyster drill feeding rates. Comparison of intertidal and subtidal sites is important because aerial exposure decreases oyster drill feeding rates (Brown & Stickle 2002). Specifically, we quantitatively sampled and measured oyster drills for a year at three locations (one coastal and two estuarine) and tagged snails at each location and caged them to follow growth in two seasons and reproductive activity during the egg-laying season in 1 yr. To integrate these life history data, we calculated rates of secondary production at each site, which combines in a single measure life history parameters like density, biomass, individual growth, development time, recruitment, and mortality (Benke 1993, Taylor 1998).

We also discuss what environmental factors may cause the variation, and provide information on two possible causes, food availability and predation risk. Prey abundance and quality have been shown to affect the ecology of thaidid snails on other coastlines (Palmer 1983, Spight 1982). The degree of predation risk can reduce feeding rates (Richardson & Brown 1992), lower growth rates, and result in increased shell thickness as a defensive mechanism (Palmer 1990). To evaluate the relative importance of prey availability and predation risk for *Stramonita haemastoma*, we (1) added oyster prey at a site where only barnacle prey were available, and (2) assessed predation risk by estimating the abundance of the stone crab (*Menippe adina*) and looked for differences among oyster drill populations in shell thickness.

MATERIALS AND METHODS

Site Descriptions

The three locations [for a map of locations, see Brown and Swearingen (1998)] are approximately 140 km south of New Orleans (29°10'N, 90°05'W). Caminada Pass (the exposed site, = CP) is the narrow mouth of Barataria and Caminada Bays, an extensive estuary system southeast of New Orleans. Strong currents occur during tidal flows, and CP is fairly exposed to wave action from the Gulf. Using plaster casts, Richardson and Brown (1990) found that over three-quarters of the mass was lost over a 2-day interval at this site (Table 1), indicating much greater levels of exposure and flow than at the estuarine site, where only one-fifth of the mass was lost on average. Average temperatures vary from 12°C during winter months to 30°C during summer months (Fig. 1), and salinities average 26 psu (practical salinity scale, Table 1). By far the most common prey at this site are barnacles (*Balanus eburneus*) (Table 1).

The other two locations, near the Louisiana Universities' Marine Consortium laboratory at Port Fourchon, Louisiana, about 20 km west of Caminada Pass and 10 km inland from the mouth of Bayou Fourchon, are more estuarine (Table 1). The first location is an intertidal oyster reef (= Laboratory Int) in a *Spartina alterniflora* marsh, and the second site is a subtidal reef (= Laboratory

Fourchon Lab	22 (16–28)	21%	Numbers/M ²	222 ± 9.5	13,885 ± 1,273
			Size	79.2 ± 56.7 g	11.0 ± 3.0 mm ²
Caminada Pass	26 (18–34)	79%	Numbers/M ²	4.0 ± 0.3	65,215 ± 8,310
			Size	10.6 ± 3.1 g	9.0 ± 1.2 mm ²

Standard errors are given for prey abundances and sizes. Oyster sizes refer to total wet mass (including shell). Barnacle sizes are basal areas. Data on prey abundance taken from Brown (1997), Brown and Swearingen (1998), McCoy and Brown (1998), and Banks and Brown (2002).

Sub) 50 m from the intertidal reef. Both sites are heavily colonized by oysters, with densities over a 5-yr period (pooled over both tidal heights) 50 times greater than at the exposed site (Table 1). Barnacle density, in contrast, is greater at the exposed site. The data in Table 1 were collected over a 5-yr period using quadrat sampling for oysters and colonization plates for barnacles (for more details, see papers given in Table 1).

Sampling

We quantitatively sampled all three locations (Table 2) on a monthly basis from August 1998 to October 2000 by haphazardly placing out 10–16 m² quadrats during low tide. Each quadrat was first searched visually to remove larger oyster drills, and oyster shell was then rinsed over a sieve to locate smaller drills (although we undoubtedly missed small, recently recruited individuals). All snails were measured to the nearest 0.1 mm. A two-way analysis of variance (ANOVA) was used to contrast densities and shell sizes among locations and through time. Locations were considered a fixed effect because they were selected to contrast different levels of exposure or tidal height, and dates were considered fixed effects as they were selected so that each month was represented to allow calculation of monthly production estimates. Density data were log-transformed to improve normality.

To assess differences in predation risk among sites we (1)

trapped crabs at Caminada Pass and the subtidal, estuarine reef, and (2) assessed differences in shell lip thickness of oyster drills at both sites. We fished six, baited crab traps at each site for two nights, on three dates (summer through fall 2001) and pooled all crabs collected per date at each location. Crab catch per unit effort (CPUE) data were log-transformed and subjected to a two-way ANOVA (two crab species \times two locations with the three dates as replicates), and data were also analyzed in a nonparametric analog of the two-way ANOVA, the S. R. H. modification of the Kruskal-Wallis test (Sokal and Rohlf 1995).

Secondary Production

To estimate biomass from shell length, 100 snails from Caminada Pass and the subtidal, estuarine oyster reef were measured to the nearest mm, and tissue was dried at 60 C for 24 h. Dry tissue mass was estimated using the following equation ($R^2 = 0.95$, $P < 0.0001$):

$$g \text{ dry mass} = (1.8 \times 10^{-6})(\text{shell length})^{3.46}$$

Monthly, size-specific production (g dry tissue mass/m²) at each site was estimated using the instantaneous growth method (Benke 1996, Waters 1977). The size-specific instantaneous growth rate was estimated from the growth of similar-sized snails in experiments, and monthly, size-specific biomass estimates (g dry tissue mass/m²) from field samples. For each time interval, growth was averaged for all individuals within each millimeter size class and applied to size-specific, mean monthly biomass estimates. Production was calculated for each millimeter size class, then summed to estimate monthly production.

Growth Experiments

Two experiments were conducted from December 1998 to April 1999 and from June 1999 to August 1999 (Table 2) to assess seasonal differences in growth rates. Snails from Caminada Pass and the subtidal, estuarine oyster reef (but not the intertidal reef because of low snail abundance, see "Results") were mixed to produce a size range, and 10 individuals in each of four different size categories (averaging 30, 40, 50, and 60 mm mean shell length ± 1 mm SE) were placed separately in cages at all three locations. Cages were plastic trays (60 cm \times 75 cm \times 15 cm high) covered with 3-mm vexar mesh, and placed on the bottom and held fast by cable ties to PVC poles embedded 1 m in the sediment at all four corners. There were four replicate cages for each size class at each location. Snails were tagged with numbered bee tags attached with super glue and were measured (tip of spire to tip of aperture) to the nearest 0.1 mm with a Vernier caliper and weighed to the nearest

TABLE 2.

Summary of what sampling and experiments were conducted at each of the three locations, along with the types and periodicities of data collected.

Location	Field Sampling	Growth Experiments	Reproduction Experiment	Prey Addition Experiment
Lab Int.	X	X		
Lab Sub.	X	X	X	
Caminada Pass (= CP)	X	X	X	X
Data	Density, size distribution, production (g dry mass/M ²)	Individual growth (mm)	Numbers of egg capsules, numbers of embryos per capsule	Individual shell growth (mm) and capsules per cage
Periodicity and length	Monthly for 1 yr	Monthly for 3 mo	Monthly for 2 mo	Monthly for 2 mo

milligram with an analytical balance at the start and monthly through the end of the experiment.

The most common prey at Caminada Pass were barnacles that rapidly recruit to subtidal surfaces (see discussion above), and we simply allowed prey to colonize cages. At the two estuarine locations, we added 20 oysters (from 50 to 150 g wet total mass per oyster) to each cage to approximate the abundance and size range of oysters available at the locations (Brown 1997). As cages were checked monthly, oysters were added to replace those consumed (at the estuarine locations), and the mesh was cleaned to facilitate water circulation.

Gastropod growth rates are dependent on size, and we used Ford-Walford plots (Fig. 2) to illustrate how shell growth increments were related to initial shell length (Eter 1989). Plotted data are the total shell growth increment over the experiment versus initial size for each snail surviving the experiment. However, because 10 snails were placed in each cage, using individual snails as replicates in statistical analyses could be considered pseudoreplication. We therefore also used the average shell length per cage as the experimental unit and performed a repeated measures ANOVA to test for time effects (e.g., change in size since oyster drills were measured monthly), as well as the location effect and the location times time interaction (Proc GLM, Statistical Package (SAS) Inc., 1988).

Reproduction Experiments

These experiments (Table 2) were conducted in April 1999 through May 1999, during the peak of the oyster drill egg-laying season, at Caminada Pass and the subtidal, estuarine oyster reef (experiments were not replicated at the intertidal site because of low ambient snail densities). The same four size classes, with three replicate cages for each size class, each with 10 oyster drills, were deployed at each location in the same fashion as in the growth experiments. Cages were checked monthly, and all egg capsules removed. A randomly selected subset of five capsules from each cage was preserved in 70% ethanol and counted at 7× magnification to estimate embryo number. Southern oyster drill eggs hatch in approximately 2 wk (Roller & Stickle 1988), but capsules continue to adhere to surfaces, so monthly counts were not underestimates. Preliminary data indicated counting the embryos in five egg cases gave an accurate estimate of the average number of embryos per capsule. We used two-way ANOVAs to test for significant differences among locations and oyster drill shell lengths in number of capsules produced and average number of embryos per capsule. Data were checked for normality with procedure.

Figure 2. (A) Ford-Walford plot of total shell growth increment against initial shell length for oyster drills caged at three locations in the winter 1998–1999 growth experiment, along with fit regression lines and correlation coefficients. CP = Caminada Pass, Laboratory Sub = subtidal oyster reef at Port Fourchon, Laboratory Int = intertidal oyster reef at Port Fourchon. (B) Ford-Walford plot of shell growth increment against initial shell length for oyster drills caged at three locations in the summer 1999 growth experiment along with fit regression lines and correlation coefficients. CP = Caminada Pass, Laboratory Sub = subtidal oyster reef at Port Fourchon, Laboratory Int = intertidal oyster reef at Port Fourchon.

Univariate (SAS Institute 1988) but transformation was not necessary. Tukey's *a posteriori* tests were used to determine which means differed.

Prey Addition Experiment

To determine if reduced growth and fecundity at Caminada Pass were explained by the absence of high-quality prey, we added 20 oysters (wet total mass from 50 to 150 g per oyster) to cages and compared growth and fecundity to control animals in cages with "ambient" prey. On March 28, 2000, six control and six experimental cages were placed at Caminada Pass at the same site and in the same fashion as in earlier experiments. Each cage had 10 marked oyster drills (mean shell length \pm SE, control = 44.8 ± 1.2 , experimental = 45.9 ± 1.2) and was retrieved after 2 mo. Two control cages were damaged, but increments in average shell length and total number of capsules produced were contrasted between the four remaining control and six experimental cages in a one-way ANOVA.

RESULTS

Density, Size, and Secondary Production

Oyster drill densities varied significantly among the exposed and two estuarine locations ($F = 130.0$, $P < 0.0001$), months ($F = 22.3$, $P < 0.0001$), and a significant interaction occurred between location and month ($F = 15.7$, $P < 0.0001$). Overall, densities were highest at Caminada Pass, intermediate at the subtidal, estuarine oyster reef, and lowest at the intertidal oyster reef (Table 3). However, densities fluctuated considerably through time (Fig. 1), explaining the significant interactions between location and month.

There were also significant differences among the three locations ($F = 365.3$, $P < 0.0001$) and through time ($F = 160.1$, $P < 0.0001$) for average shell length as well as a significant interaction ($F = 127.2$, $P < 0.0001$). Tukey's *a posteriori* tests indicated oyster drills were largest at the intertidal estuarine oyster reef (Fig. 3, Table 3), intermediate in size at the subtidal, estuarine oyster reef, and smallest at Caminada Pass.

Unlike density, average biomass was higher at the subtidal estuarine oyster reef than at Caminada Pass (Table 3), reflecting the greater number of large snails at the estuarine, subtidal location. Mean monthly biomass at the intertidal reef location was much lower. Peak biomass among all locations was observed in April 1999 at the subtidal oyster reef, when biomass exceeded 20 g/m^2 . The higher biomass and markedly greater individual growth rates at the subtidal, estuarine oyster reef (see next section) resulted in a 10-fold higher average monthly production in comparison to Caminada Pass (Table 3).

TABLE 3.

Average oyster drill density per M^2 , shell length (mm), biomass (g per M^2), and production (g per M^2), \pm SE ($n = 12$ mo) at three locations along the Louisiana Gulf of Mexico coast.

Location	Density	Size	Biomass	Production
Lab Sub.	6.25 ± 2.52	49.6 ± 1.0	8.01 ± 1.36	1.46 ± 0.20
Lab Int.	0.04 ± 0.02	77.2 ± 2.7	0.74 ± 0.49	0.02 ± 0.01
Caminada Pass	11.40 ± 4.10	34.6 ± 2.0	4.04 ± 0.85	0.14 ± 0.03

Figure 3. Size distributions of all southern oyster drills collected during sampling at the three locations along the Louisiana Gulf coast. CP = Caminada Pass, Laboratory Sub = subtidal oyster reef at Port Fourchon, Laboratory Int = intertidal oyster reef at Port Fourchon.

Predation Risk

Crab CPUE values differed among the two crab species, with blue crabs much more abundant than stone crabs (Table 4). The species effect was significant ($F = 20.0$, $P < 0.001$), unlike the location effect ($F = 0.01$, $P = 0.98$) and interaction ($F = 2.5$, $P = 0.12$). The nonparametric test also indicated a significant species effect ($H = 6.9$, $P < 0.05$), and insignificant location ($H = 0.2$, $P > 0.05$) and interaction ($H = 3.7$, $P > 0.05$) effects. Blue crabs had somewhat larger carapace widths than stone crabs (Table 4), but stone crabs with a carapace width of 9 cm are readily capable of feeding on oyster drills (Brown & Haight 1992). There were no significant differences in oyster drill shell lip thickness among locations (Table 4, $F = 0.5$, $P = 0.62$), although total shell length had a highly significant effect on shell lip thickness ($F = 18.3$, $P < 0.001$). The lack of a significant interaction ($F = 0.4$, $P = 0.7$) indicates no difference in slopes of lines relating lip thickness to shell length among locations, and the slightly greater lip thickness of oyster drills at the estuarine, subtidal oyster reef therefore appears primarily due to their greater average shell length (Table 4).

Growth Experiments

There were significant differences in growth among the three locations in both experiments, with higher growth rates at the subtidal, estuarine oyster reef. Although the repeated measures ANOVA of the winter 1998–1999 data detected no time (e.g., month) effect (Wilk's $\lambda = 0.53$, $F = 1.1$, $P = 0.45$), there was a significant interaction between time and location (Wilk's $\lambda = 0.062$, $F = 3.8$, $P < 0.05$), and a significant difference among locations ($F = 37.9$, $P < 0.001$). The covariate, initial size, also

TABLE 4.

Crab catch per unit effort for two species of crabs, crab carapace widths (in cm), and oyster drill shell lip thickness and total shell length (both in mm), at two locations along the Louisiana Gulf of Mexico coast.

Location	Trait	Blue Crab	Stone Crab	Drill Shell Thickness	Drill Shell Length
Fourchon Lab	CPUE	60.7 ± 46.6	2.3 ± 1.5	0.75 ± 0.04	55.2 ± 0.9
	Carapace width	12.8 ± 0.3 (182)	9.4 ± 0.2 (7)		
Caminada Pass	CPUE	45.7 ± 15.5	1.0 ± 0.2	0.57 ± 0.03	41.9 ± 0.5
	Carapace width	13.8 ± 0.1 (137)	8.5 ± 0.1 (3)		

All values are means and standard errors. Thirty oyster drills were measured at each site, and numbers in parentheses are the number of crabs measured. CPUE, crab catch per unit effort.

had a significant effect on growth ($F = 53.1$, $P < 0.001$). Portraying the results of this winter growth experiment as Ford-Walford plots (Fig. 2A) clearly illustrates the greater growth rates of smaller oyster drills at the subtidal oyster reef, as well as the significant effect of the covariate. The same basic pattern occurred in the summer 1999 experiment, although growth rates overall were somewhat lower (Fig. 2B). The repeated measures ANOVA again detected no time effect (Wilk's $\lambda = 0.79$, $F = 0.57$, $P = 0.65$), a significant interaction between time and location (Wilk's $\lambda = 0.066$, $F = 5.8$, $P < 0.01$), and a significant difference among locations ($F = 33.9$, $P < 0.001$). The covariate, initial size, again had a significant effect on growth as well ($F = 40.3$, $P < 0.001$).

Reproduction Experiment

There were clear differences between the two locations (with values again greater at the subtidal, estuarine oyster reef than at the exposed location) and oyster drill size classes in number of egg capsules deposited per cage (Fig. 4A). Both the location ($F = 29.7$, $P < 0.0001$), shell length ($F = 5.2$, $P < 0.01$), and location times shell length interaction terms ($F = 5.2$, $P = 0.01$) were significant in the ANOVA. Comparing Tukey's *a posteriori* tests among size classes within locations, there were no significant differences among size classes at Caminada Pass. However, at the subtidal, estuarine oyster reef, the largest snails (60 mm) overlapped with the next largest (50 mm) but not the two smaller size categories of snails, whereas the snails averaging 50 mm overlapped with the 40-mm snails but not the 30-mm size category, and the 40-mm- and 30-mm-sized snails overlapped as well. Comparing locations within size classes, oyster drills laid more egg capsules at the subtidal, estuarine oyster reef than at Caminada Pass in both of the larger size classes, but not in the smaller size classes.

Average number of embryos per capsule also varied significantly among locations (again greater at the subtidal, estuarine oyster reef, $F = 5.6$, $P = 0.03$) and size classes ($F = 31.1$, $P < 0.0001$), without any interaction (Fig. 4B). Oyster drills at the subtidal, estuarine oyster reef produced on the average 2,021 embryos per capsule versus 1,598 at Caminada Pass. *A posteriori* tests indicated the largest oyster drills produced significantly more embryos per capsule than the other three size classes, while the two intermediate classes overlapped, as did the 30- and 40-mm shell-length oyster drills. These values compare with average embryo numbers per capsule of about 3,200 for snails greater than 40-mm shell length held under laboratory conditions (Roller & Stickle 1988). Multiplying average numbers of egg cases times average embryo counts, and assuming five of the snails were females, per capita fecundity at Caminada Pass was approximately 35,000 versus 1,020,000 at the estuarine oyster reef.

Prey Addition Experiment

Addition of oyster prey to cages at the exposed site (= CP) resulted in both increased growth in oyster drill shell length ($F = 7.4$, $P = 0.02$) and higher production of egg capsules ($F = 11.5$, $P = 0.01$) in comparison to control cages. Growth in shell length

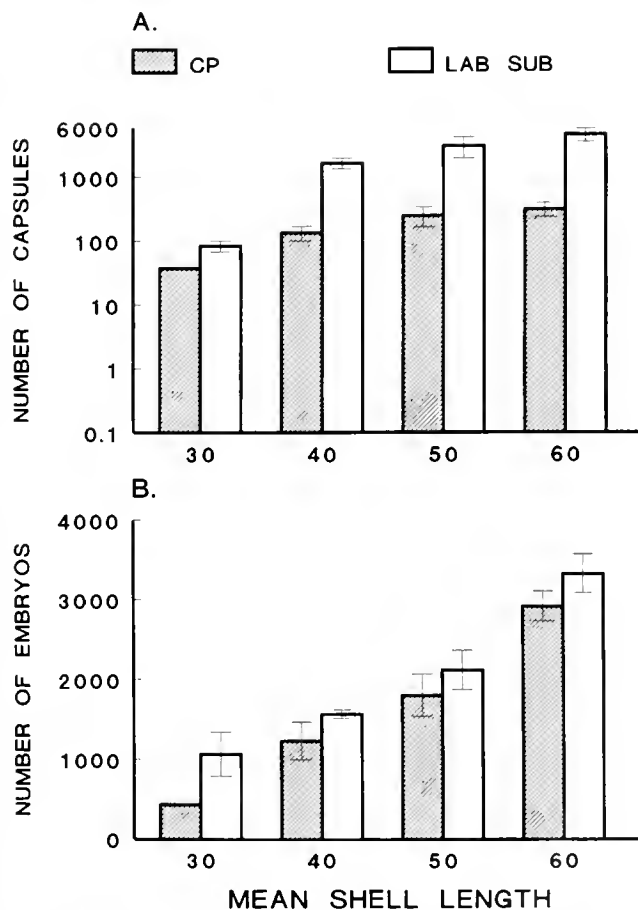

Figure 4. (A) Semi-logarithmic plot of size-specific differences in number of egg capsules deposited per cage ($\bar{x} \pm SE$, $n = 4$) at two locations along the Louisiana Gulf coast. CP = Caminada Pass, Laboratory Sub = subtidal oyster reef at Port Fourchon. The standard error is missing for the smallest snails at CP because only one cage had egg cases. (B) Size-specific differences in numbers of embryos per egg capsule per cage ($\bar{x} \pm SE$, $n = 4$) at two locations along the Louisiana Gulf coast. CP = Caminada Pass, Laboratory Sub = subtidal oyster reef at Port Fourchon.

was greater in experimental treatments by a factor of eight, and production of egg capsules increased by a factor of four (Fig. 5).

DISCUSSION

In general, intraspecific life history variation in intertidal gastropods is usually explained as the result of three factors acting singly or in combination: (1) differences in prey quantity or quality (Palmer 1983, Palmer 1984, Spight 1982), (2) differences in wave action (Brown & Quinn 1988, Denny et al. 1985, Richardson & Brown 1990), or (3) variation in predation risk (Palmer 1990, Richardson & Brown 1992). In *Stramonita haemastoma*, a combination of these factors probably explains variation among locations in life history patterns. The dominant prey at Caminada Pass, the barnacle *Balanus eburneus*, may not be as conducive to producing growth as oysters, the most common prey at the estuarine locations, explaining the increased growth and fecundity of the oyster drills in cages with added oysters at the exposed site. Although there is yearly variation in abundance, especially for barnacles, oysters were consistently more abundant at the estuarine sites over time in this study, and this same trend occurs at other locations along the Gulf of Mexico coast, and the lower Atlantic coast of the United States as well (Bahr & Lanier 1981, Brown & Swearingen 1998, Chatry et al. 1983, Roegner & Mann 1995, Wilber 1992). However, the increased tidal flows and wave action at the exposed site could also reduce growth (Richardson & Brown 1990), and the effects of food value and wave action are thus likely confounded. Increased wave action can also directly reduce average sizes in exposed populations by dislodging the largest individuals (Denny et al. 1985).

Although we worked with only one location within each exposure or tidal height category, we consider our results to have some generality because these trends to a large extent agree with other studies on this and other intertidal snail predators. Brown and Richardson (1987) recorded higher densities and smaller-sized individuals of *Stramonita haemastoma* at exposed locations in comparison to protected locations, and others have also found considerable variation in intertidal gastropod densities and size distributions among locations and seasons (Carroll & Highsmith 1996, Navarette 1996, Petraitis 1998). The greater growth at the subtidal,

estuarine oyster reef than at the exposed location is similar to earlier studies of *Nucella lapillus* (Eter 1988, Eter 1989, Eter 1996) and *Nucella emarginata* (Brown & Quinn 1988). However, Eter (1989) also found increased fecundity at exposed locations. Differences in growth rates in *N. lapillus* are the result of ecophenotypic variation, not genetic differences among populations (Eter 1988, Eter 1996). *Stramonita haemastoma* has a relatively long pelagic larval stage, lasting 90 days, and there is considerable gene flow among populations in the northern Gulf of Mexico (Liu et al. 1991), arguing against high levels of genetic variation among these populations, which are only separated by tens of kilometers. The prey manipulation experiment also suggests that oyster drill growth and reproductive rates are plastic and will respond to increased food availability.

Oyster drills in the northern Gulf of Mexico reach 30 mm in shell length and usually reproduce in their first year (Butler 1985). However, the slow growth and small sizes attained by the oyster drills at Caminada Pass (average oyster drill size was only 35 mm) may mean they do not reproduce until their second spring, and senesce shortly afterwards. This could explain the peak recruitment at Caminada Pass in only 1 yr of the study, as a cohort matured, reproduced, and senesced. In contrast, at the subtidal protected oyster reef, rapid growth may have resulted in reproduction in the first year, and individuals probably survive and reproduce for several years (average size was around 50 mm, and iteroparity may also explain the bimodal size distribution at this site shown in Fig. 3). Such iteroparous reproduction has also been reported before in southern oyster drills (Butler 1985).

Our results indicate that wave exposure along the relatively protected Louisiana Gulf of Mexico coastline does not have as extreme an effect on life histories as it does in thaidid snails along other coastlines. Wave exposure may have a more indirect effect, by altering the abundances of prey organisms (oysters again recruit more readily at estuarine locations) or forcing oyster drills to consume smaller, suboptimal prey (Richardson & Brown 1990). Nor does predation risk appear as important as for thaidids along other coastlines, as we could detect no differences in the abundances of stone crabs among locations; in fact stone crabs were relatively rare in comparison to blue crabs, which are effective predators only on small, recently settled oyster drills (Butler 1985). If anything, predators like stone crabs or black drum are probably more abundant in the northern Gulf of Mexico at higher salinity coastal sites (Brown et al. 2003), and the increased predation risk seen at protected sites for thaidids on other coastlines either does not occur in this system or may even be reversed, with higher predation rates at coastal sites. The lack of any difference in shell lip thickness among locations also provides indirect support for the lack of any differential in predation risk among sites.

We conclude that prey value and availability appear most important in explaining intraspecific life history variation in southern oyster drills, as both growth and reproductive rates responded with four- to eight-fold increases when oyster prey were provided to snails held at exposed sites. This result is certainly consistent with other studies suggesting that prey value and availability may determine thaidid growth rates (Palmer 1983) and recruitment (Spight 1975, Spight 1982).

CAPTIVE BREEDING BEHAVIOR OF FOUR STROMBIDAE CONCH

AMBER L. SHAWL AND MEGAN DAVIS

Harbor Branch Oceanographic Institution 5600 US 1 North, Ft. Pierce, Florida 34946

ABSTRACT The feasibility of a captive breeding program was examined for the protected fisheries species *Strombus gigas* (queen conch) and three nonprotected Caribbean *Strombus* conch species: *S. raninus* (hawk-wing conch), *S. alatus* (Florida fighting conch), and *S. costatus* (milk conch). A total of 24 adult conch were collected from the Florida Keys: five *S. costatus* (three females, two males), seven *S. raninus* (five females, two males), eight *S. alatus* (four females, four males), and four *S. gigas* (one female, three males). The conch were placed in a 4.5-m dia circular tank that was divided into four equal quadrants (4.1 m²). The conch were fed a prepared gelatin diet made of Mazuri® Kor chow blended with *Ulva* sp. Egg masses collected from the breeding tank were measured for size, number of eggs, and diameter of egg capsule and strand. In the 40-week study, 426 egg masses were collected, and egg laying activity appeared to be related to water temperature. A total of 341 egg masses were collected from the five *S. raninus* females. The four *S. alatus* females laid 58 egg masses, the three *S. costatus* females laid a total of 23 egg masses, and the single *S. gigas* female laid four egg masses. The viability of egg masses from all four species was confirmed by successfully hatching and culturing the larvae to the juvenile stage. All species except *S. gigas* laid egg masses while copulating. Mate preferences and guarding behavior was observed. The captive breeding of these species holds promise for the establishment of a commercial captive breeding program, and may provide alternative conch species for the food and aquarium market.

KEY WORDS: conch, culture, larvae, reproduction, spawning, *Strombus*

INTRODUCTION

Six *Strombus* species¹ inhabit the shallow coastal waters of Florida and the Caribbean region: *Strombus gigas* Linnaeus (queen conch), *S. costatus* Gmelin (milk conch), *S. raninus* Gmelin (hawk-wing conch), *S. alatus* Gmelin (Florida fighting conch), *S. pugilis* Linnaeus (West Indian fighting conch), and *S. gallus* Linnaeus (rooster-tail conch; Abbott 1974). Of these species, *S. gigas* holds the highest commercial value as a subsistence and commercial fisheries product (Berg 1976, Brownell 1977, Appeldoorn 1994). *S. costatus* is also a highly valued fisheries species in Mexico (Aldana-Aranda et al. 1989).

Overfishing and the decline of the *S. gigas* fishery began in the 1970s and led to the enactment of several regulations and management strategies to protect conch populations (Appeldoorn 1994). A statewide moratorium on queen conch harvesting in Florida began in 1986 (Florida Administration Code, Chapter 68B-16.005), and in 1992, *S. gigas* was added to Appendix 2 of the Convention for the International Trade of Endangered Species (CITES) legal mandate. Countries that export queen conch must possess a CITES permit, which helps to ensure that harvest rates remain low enough to maintain a viable fisheries population. In addition to employing management strategies to protect wild populations, culturing queen conch for stock enhancement and commercial markets will also offset fisheries pressure (Creswell 1994, Davis and Shawl (2004a).

Florida and Caribbean *Strombus* species breed in shallow waters in seagrass beds or sandy habitats (Robertson 1959, Berg 1975, Brownell 1977, Bradshaw-Hawkins 1982, Davis et al. 1984). The reproductive season is typically during the summer months; however, some species have been observed to lay eggs year-round in certain locations (Robertson 1959, Brownell 1977, Bradshaw-Hawkins 1982). Depending on the species, the sand-covered, crescent-shaped egg mass contains between 92,000 and 400,000 eggs (Robertson 1959, Randall 1964, D'Asaro 1986, Davis et al. 1993).

Commercial and research facilities that culture juvenile queen

conch depend upon field collected egg masses (Davis 2000a). In some locations, it is difficult to find egg masses in the wild due to limited spawning aggregations. Establishing a captive breeding program for *S. gigas* and other *Strombus* species would alleviate the need to collect egg masses from the wild and may possibly extend the 6-month breeding season to year-round (Davis et al. 1984). Captive breeding and egg-laying has been observed for some *Strombus* conch species. The reproductive behavior and larval cycles of wild and captive *S. pugilis* have been described (Bradshaw-Hawkins 1982); captive laid egg masses from *S. raninus* broodstock were used to record shell morphology and larval development (Davis et al. 1993); and the reproductive behavior and anatomy of captive *S. raninus*, *S. gallus*, *S. costatus*, *S. alatus*, and *S. pugilis* were observed (Reed 1995a, 1995b). *S. gigas* have been observed to copulate in captivity (Davis, personal observation); however, there are no reports regarding egg mass laying in captivity.

Based on the available reproductive data, it is hypothesized that adult *S. gigas* and other *Strombus* species can reliably lay egg masses in captivity. Therefore, the goal of this study was to determine the feasibility of establishing a captive breeding program for *Strombus* species. To address this goal, the first objective of this study was to observe and describe the spawning activity of the protected fisheries species *S. gigas* and three nonprotected *Strombus* species: *S. raninus*, *S. alatus*, and *S. costatus* in a breeding tank. The second objective was to confirm the viability of the captive laid eggs by culturing the larvae to the juvenile stage. The results from this study will assist in developing a year-round culture program, alleviating the field collection of egg masses, and establishing alternative species for the *Strombus* markets.

MATERIALS AND METHODS

The captive breeding study was conducted at Harbor Branch Oceanographic Institution (Harbor Branch), Aquaculture Division in Ft. Pierce, Florida. Egg masses were collected for 40 weeks (June 15, 2000, to March 22, 2001), and breeding behavior observations were made daily during the first 7 weeks of the study (June 15 to August 2, 2000). Larvae hatched from the egg masses laid in captivity were cultured throughout the study period.

^a *S. costatus* were collected and held in a recirculating system for 2 weeks prior to being transported to HBOI.

^b Hatchery reared from *S. gigas* eggs collected in Florida waters.

The number of conch collected for this study was based on the availability of the conch at the collection sites. Seven adult *S. raninus* (two males and five females) and four *S. alatus* (three males and one female) were collected from three sites off Plantation Key in the Upper Florida Keys on June 15, 2000. On July 12, 2000, four additional *S. alatus* (one male and three females) were collected from the same location (Table 1). Five *S. costatus* (two males and three females) were collected on June 1, 2000, from the Ligumuiti Channel in Indian Key in the Upper Florida Keys and were placed in recirculating holding tanks in the Florida Keys for 2 weeks prior to the beginning of the study. Four hatchery-reared *S. gigas* (three males and one female) were obtained on July 12, 2000, from the Florida Fish and Wildlife Conservation Commission laboratory in Marathon, FL.

The sex of each conch was determined by positioning them on their side and observing a verge or an egg groove when it righted itself (Davis et al. 1984; Fig. 1). A small area on the dorsal side of the shell was then scrubbed clean with sandpaper and the conch were numbered with fluorescent paint (teal for males and orange for females), which was sealed with clear epoxy glue. The conch were transported in a cooler with seawater moistened towels during the four hour drive to Harbor Branch. Before being placed into the breeding tank at Harbor Branch, all of the conch were weighed to the nearest 0.1 g, and their shell lengths (SL) were measured with calipers (mm; Table 2).

The 11,500-L breeding tank (4.5 m dia × 0.7 m depth) was on a recirculating culture system (Fig. 2). The initial and replenishment water (30 L/hr or 6.5%/d) for the system was pretreated water drawn from a shallow salt water well. For the study, the breeding tank was divided into four equal areas (4.1 m²) using 30-cm high polypropylene mesh (2.5-cm openings). The tank was equipped with a raised substrate comprised of approximately a 10-cm depth of sand supported 15 cm above the bottom of the tank. The crushed coral aragonite sand (1–3-mm dia) provided substrate for the broodstock to lay egg masses and served as the biofilter for the system. The water depth above the substrate was 45 cm. The

recirculating water entered the tank both through angled spray bars above the water and substrate and underneath the substrate. The water filtered through the sand, drained through a center bottom drain, then flowed through a sand filter (Baker Hydro 363 kg) prior to returning to the breeding tank. The sand filter was backwashed every 2 weeks.

The conch were stocked at varying densities and sex ratios based on the availability of the adults found at the collection sites. *S. raninus* conch were held at 1.7 conch/10 m² at a 3:1 female:male ratio. *S. alatus* were stocked at 2.0 conch/10 m² at a 1:1 sex ratio, *S. costatus* were at 1.2 conch/10 m² at a 1:1 ratio, and *S. gigas* were held at 0.98 conch/10 m² at a 1:3 female:male sex ratio.

Temperature, salinity, and pH were recorded daily and ammonia was measured weekly using a HACH® Ammonia test kit

<i>S. gigas</i>	M	3	180–190	183.3	1094–1560	1267
	F	1	190	190	1151	1151

(Model NI-SA). The breeding tank was located within a shaded greenhouse, and natural light was supplemented with artificial lighting (250 watts) for a 12-h cycle (8 am to 8 pm). In an attempt to extend the breeding season, the tank water was heated using a 4000-watt (Titanium Single Phase "L"-Shaped Bottom Heater) heater during the winter months (November 2000 to March 2001).

The conch were fed a diet of Mazuri® Koi pellets, which were blended with dry *Ulva* sp. (sea lettuce), gelatin, and seawater to create a gelatin based benthic diet (R. LeRoy Creswell, personal communication 2000). The recipe was composed of 36% Mazuri Koi pellets, 16% *Ulva* sp., 42% seawater, and 5% gelatin. The gelatin allowed the food to remain stable for approximately 48 h. The conch were fed to satiation once per day. On average, a total of 745–925 g of gel food was fed once daily, with approximately 145 g per day fed to all the *S. raninus* conch, 150 g fed to the *S. alatus* conch, 300 g fed to *S. costatus*, and 240 g fed to the *S. gigas* conch.

Egg mass production was recorded daily. During the first seven weeks, copulatory behavior observations were made approximately five times per 24 h. Each observation spanned 15 min to one hour and included periodic night observations. The number of copulations, mate preferences, and any territorial male behavior were recorded. When an egg mass was found, it was removed with a net or by hand and placed onto a wet table for length, width and height measurements. Several egg masses were uncoiled to estimate the total length of the egg strand ($n = 13$ for *S. raninus*, $n = 10$ for *S. alatus*, and $n = 10$ for *S. costatus*). None of the *S. gigas* egg masses were uncoiled because of the limited number of masses

and the need for eggs for larval production. Measurements of egg strand diameter ($n = 5$ per egg mass), egg capsule diameter ($n = 5$ per egg mass), and the number of eggs per millimeter ($n = 3$ per egg mass) were recorded using a compound microscope (40X) equipped with an eyepiece micrometer. A total of 71 egg masses were used for this data collection: 40 for *S. raninus*, 20 for *S. alatus*, nine for *S. costatus*, and two for *S. gigas*.

Larvae of *S. raninus* (two egg masses), *S. alatus* (six egg masses), and *S. costatus* (one egg mass) were hatched from captive laid egg masses. The larvae were cultured at 20–50 veligers/L in two to three 5-L containers using established techniques (Davis 2000b). The culture water was 5- μ m filtered, UV-treated, and changed daily. The cultures were not aerated, and temperature was controlled by placing the containers in a water bath. Depending on age, the veligers were fed 3,000–20,000 cells/mL of culture water of Tahitian Isochrysis daily.

One *S. gigas* egg mass was cultured in a 420-L conical tank (Davis and Shawl, in press). The culture water was 5- μ m filtered and UV treated. An airlift provided circulation in the tank, and the water was changed every other day. The larvae were fed 5,000–25,000 cells/ml of culture water of Isochrysis, and starting on day 15, *Chaetoceros gracilis* or *Chaetoceros muelleri* was also added to the tank at a concentration of 3,000 cells/mL of culture water.

Metamorphosis was induced for all four species using diluted 3% hydrogen peroxide (Boettcher et al. 1997) or *Laurencia poitei* seaweed extract (Davis et al. 1987). A total of 529 larvae were tested: 305 larvae were induced with hydrogen peroxide, and 224 were induced with *Laurencia* extract. The SL of the newly hatched veliger (μ m), the number of days until metamorphosis, and the veliger SL at metamorphosis (μ m) was recorded along with the metamorphic success using the two inducers.

RESULTS

From June 15, 2000, to March 22, 2001 (40 weeks), a total of 426 egg masses were collected from the breeding tank. The five *S. raninus* females had the highest productivity with 341 masses, the four *S. alatus* females laid 58 masses, 23 egg masses were collected from the three *S. costatus*, and the single *S. gigas* female laid 4 egg masses. The weekly fecundity of each individual female conch was averaged. The number of egg masses per female per week per species was plotted and compared with average weekly temperature data (Fig. 3). In general, egg mass production was continuous during the warmer months, (26–29°C) June to September (Fig. 3). In the winter months, October to January, egg mass production slowed down or stopped when the temperature decreased (22–25°C). Egg mass laying began again in February

Figure 2. The Strombidae breeding tank at Harbor Branch: a) undergravel support, b) sand substrate, c) water column, d) pump, e) sand filter, and f) spray bars (drawing by Jackie Aronsan).

Figure 3. The weekly average number of egg masses collected from each female conch compared with weekly average tank and ambient temperatures for the duration of the captive breeding study at Harbor Branch (June 15, 2000, to March 22, 2001).

2001 when the temperature increased (25–29°C). By heating the breeding tank water from November 2000 to March 2001, the temperature remained 1–4°C above ambient water temperature (Fig. 3). This appeared to stimulate egg laying in the winter months (February to March 2001), as no other parameters were changed. Salinity, pH, ammonia, and nitrite remained relatively constant throughout the study (Table 3).

The weekly number of egg masses laid per species per week was standardized for each 10-week period of the 40-week study (Table 4). *S. raninus* females were the only species to lay egg masses throughout the four 10-week sample periods, with a maximum of seven egg masses collected from one female per week. The maximum number of egg masses laid from one female per week from *S. alatus* and *S. costatus* was five and three, respectively. The single *S. gigas* female did not lay an egg mass until

^c Davis et al. (1993).

^d Randall (1964).

February 2001. One egg mass was collected each week during weeks 35, 36, 38, and 39.

Egg mass characteristics of the eggs laid by the captive adults were similar to those of egg masses laid in the wild (Table 5). *S. raninus* egg masses were long and narrow and consisted of a very thin and fragile egg strand (351 ± 24 µm dia). The *S. alatus* egg masses were shorter and wider than *S. raninus* and the egg strand was slightly larger in diameter (509 ± 41 µm). *S. costatus* and *S. gigas* produced the largest egg masses with the thickest egg strands (825 ± 56 µm and 798 ± 18 µm, respectively). The *S. raninus* and *S. alatus* egg masses contained an estimated 76,000–250,000 eggs per mass, whereas the *S. costatus* egg masses held up to an estimated 440,000 eggs. The egg capsule diameter and number of eggs per mm appeared to be related to the size of the egg strand diameter. *S. raninus* egg capsules were small, therefore, each mm of egg strand contained approximately twice as many eggs as the other three species (Table 5). Females from all three species were observed to copulate consecutively with more than one male while laying the same egg mass.

From June 16 to August 2, 2000, the first 7 weeks of the study, copulatory frequency and reproductive behavior was observed for *S. raninus*, *S. alatus*, and *S. costatus*. The number of observed copulations was compared with the number of egg masses collected during that time period (Fig. 4). For *S. raninus*, the number of egg masses collected from the female conch was higher than the number of copulations observed. However, for *S. alatus* and *S. costatus* there were less egg masses collected compared with the number of copulations observed. All three species were observed copulating while laying an egg mass (Fig. 5). *S. alatus* were observed to display this behavior more frequently (52%), compared with *S. raninus* (31%) and *S. costatus* (19%; Fig. 5).

Several conch showed preferences for particular mates (Fig. 6). Using the males as examples, *S. raninus* male 1 showed no preference; he mated approximately an equal amount of the time with each of the five females. In contrast, *S. raninus* male 2 demonstrated a mating preference towards females 2 and 3. *S. alatus* male 1 showed a preference towards females 1 and 3, and male 2 showed preference towards females 3 and 4. *S. alatus* male 3 showed no preference and mated with all four females, whereas male 4 only mated with female 3. *S. costatus* male 1 copulated with all three females with approximately the same frequency; whereas, male 2 showed a preference towards female 2.

Figure 4. The total number of conch egg masses collected compared with the number of copulations that were observed from June 15 to August 2, 2000 (7 weeks).

Figure 5. The number of times a female was observed simultaneously laying an egg mass while copulating versus the number of times a female was copulating and not laying an egg mass. Observations were recorded from June 15 to August 2, 2000 (7 weeks).

Conch were observed to copulate from 5 minutes to 2 h. The males would approach the females with their proboscis to initiate an interaction. Several times the females would leap away from the male, rejecting copulation. During other observations the males would follow the females around the perimeter of the enclosure before copulation was successful. There appeared to be no trend in mating pairs based on the size of the copulating female or male.

The *S. alatus* male conch in the breeding tank demonstrated protective courting behaviors. On several occasions, two males would prop themselves halfway on the lip of an egg-laying female. Only one of the males mated with the female while the other male appeared to be "guarding" the female. Behavior similar to this was observed in *S. pugilus* (Bradshaw-Hawkins 1982). The guarding male almost always had their siphonal canal positioned 90° to and on top of the female's dorsal side. During one observation, an egg-laying female had three aggressive males around her. One of the males guarding her used his proboscis in an attempt to dislodge the male that was mating with her. When the guarding male was unable to remove the mating male, he proceeded to use his proboscis to "spar" with that male. After a few minutes, the males stopped and the guarding male attempted to move back into his position. However, as the two males were sparring over top of the female, another male moved in. The third male was immediately chased away by the guard male. The guarding male then attempted to dislodge the mating partner once again, but was unsuccessful and copulation continued. The *S. alatus* broodstock were initially stocked at a 1:1 sex ratio. A few weeks into the study, the ratio in the breeding tank was increased to 1:2.5 female: male. Once male guarding and sparring were observed, some of the males were removed to decrease the sex ratio back to 1:1 to reduce stress on the egg-laying females.

All four captive species laid viable eggs in captivity. *S. alatus*, *S. costatus*, and *S. gigas* larvae were competent for metamorphosis in 18–24 days, and *S. raninus* were competent in 48 days (Table 6). When *S. alatus* larvae were exposed to the hydrogen peroxide inducer, 69.3% ± 17.2 of the larvae metamorphosed, which was similar to larvae exposed to the Laurencia inducer (62.5% ± 10.8). The *S. costatus* larvae showed a low metamorphic success rate with hydrogen peroxide (31% ± 14.1) and an even lower rate with Laurencia (0.7% ± 1). However, the larvae that did not undergo metamorphosis with the Laurencia extract were reinduced three days later with hydrogen peroxide and 78% of these larvae com-

pleted metamorphosis. *S. gigas* larvae were only induced with hydrogen peroxide and demonstrated a metamorphic success rate of 69%. *S. raninus* larvae did not have a very high metamorphic success rate with either of the inducers (< 7%).

Veliger shell length (μm) at hatch and at metamorphosis is shown in comparison with other laboratory cultured *Strombus* veligers (Table 6). *S. raninus* veligers hatched at the smallest size (205 ± 10.5 μm) and *S. costatus* veligers had the largest SL at hatch (370 ± 10.5 μm). The *S. gigas* larvae hatched at a much smaller SL than previously observed (Davis et al. 1993). The two smaller *Strombus* species, *S. raninus* and *S. alatus* veligers, had the largest SL at metamorphosis (1438 ± 72.2 μm and 1539 ± 186 μm, respectively), although *S. alatus* larvae were competent for metamorphosis in nearly half as many days. In contrast, previous studies have reported a much larger *S. costatus* veliger at the time of metamorphosis (Brownell 1977; Table 6).

DISCUSSION

Culturing conch in captivity can reduce the harvest pressure that is evident in the fishery (Berg 1976, Brownell 1977, Creswell 1994). All four conch species used in this study spawned in captivity in a recirculating tank system. This significant breakthrough means that the culturing cycle for *S. gigas*, *S. raninus*, *S. alatus*, and *S. costatus* can be closed. Potential conch farms may no longer need to rely upon wild reproductively active adult conch populations for egg masses. Raising conch in a recirculating system minimizes effluent discharge and also suggests that future conch aquaculture sites may not need to be located near seawater sources.

The success of spawning conch in captivity was caused by several factors. The conch were provided with a stable breeding site that was devoid of predators, had optimal water quality conditions, a consistent supply of food, and a sand substrate. Temperature also appeared to regulate spawning activity. In wild adult populations, increasing temperatures throughout the summer months along with a 12-h photoperiod characterizes the reproductive season for *S. gigas* (Stoner et al. 1992). When temperature was increased artificially in early February 2001, all four species began to lay eggs again. This is typically two months sooner than spawning occurs in the wild (Davis et al. 1984). In this study, the male and female conch had been artificially aggregated, which increased the potential for mating. Wild *Strombus* adult populations are usually found at a sex ratio of 1:1. The five *S. raninus* adults produced the majority of the egg masses with only two males. This may suggest that a breeding tank can be stocked with a higher female sex ratio while still maintaining an appropriate stocking density within the breeding tank.

The *Strombus* larvae hatched from the egg masses spawned in captivity were viable. Larvae from all four species became metamorphically competent and the hydrogen peroxide inducer yielded the highest percent metamorphosis. It appears that the *S. gigas* larvae hatched at a smaller size than previously reported, which could be a result of eggs laid in an artificial habitat. *S. raninus* females were the most prolific egg layers of the four species; however, the larval cycle was twice as long as the other species. *S. alatus* larvae had the shortest larval cycle and the highest tolerance for temperature and salinity changes.

This study has demonstrated the feasibility of establishing a captive breeding program for *Strombus* species. Due to the success of this study, an expanded captive breeding area and conch hatchery was developed and is in operation at Harbor Branch to culture *S. alatus* at a commercial scale (Davis and Shawl, 2004b), and *S. gigas* for conservation research.

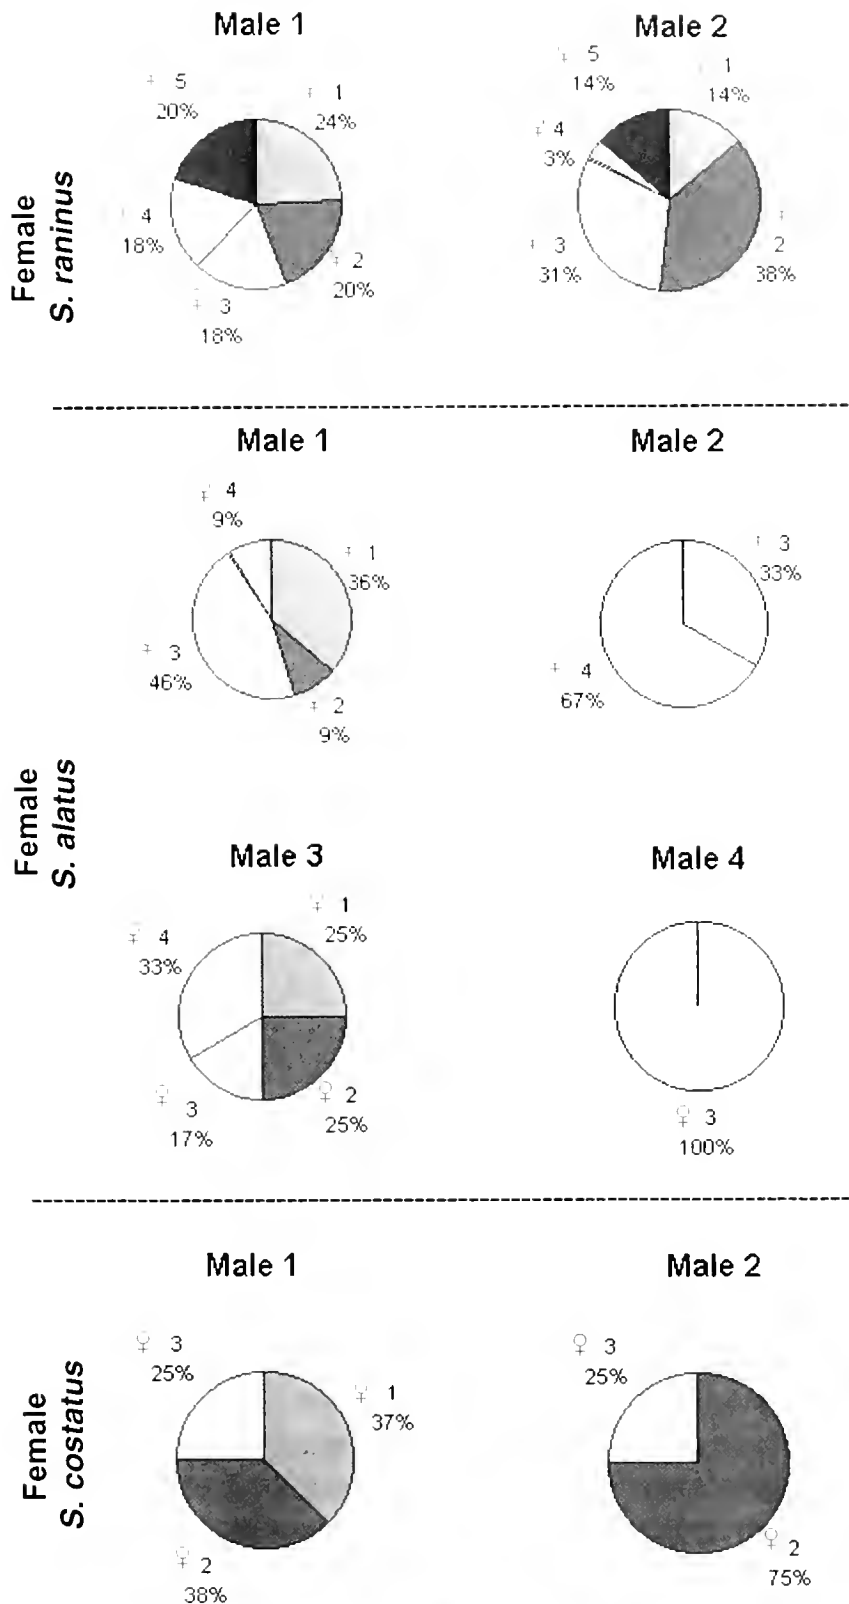

Figure 6. Male preferences towards female breeding partners. Observations were recorded from June 15 to August 2, 2000 (7 weeks).

To ensure reliable egg mass production in captivity, research must be conducted on photoperiod, temperature, density, nutrition, and sex ratio. Determining these parameters and cultivating

alternative *Strombus* species will assist in alleviating the need to collect egg masses from the wild, provide year-round egg masses, and will ultimately relieve pressures on the *S. gigas* fishery.

TABLE 6.

Summary of veliger and metamorphosis data from the study (bold numbers) compared to published data.

Variable	<i>S. raninus</i>	<i>S. alatus</i>	<i>S. costatus</i>	<i>S. gigas</i>
Newly hatched veliger SL (μm)	205 \pm 10.5 (10) 197 \pm 8 (20) ^a	298 \pm 14.2 (10) —	370 \pm 10.5 (10) 388 \pm 14 (20) ^a	221 \pm 28.4 (20) 354 \pm 15 (20) ^c

GENETIC HETEROGENEITY ANALYSIS AND RAPD MARKER DETECTION AMONG FOUR FORMS OF *ATRINA PECTINATA* LINNAEUS

XIANGYONG YU,^{1,2} YONG MAO,² MEIFANG WANG,² LI ZHOU¹ AND JIANFANG GUI^{1,*}

¹State Key Laboratory of Freshwater Ecology and Biotechnology, Institute of Hydrobiology, Chinese Academy of Sciences, Wuhan 430072, China and ²Fisheries College, Zhanjiang Ocean University, Zhanjiang 524025, China

ABSTRACT Pen shell (*Atrina pectinata* Linnaeus) can be distinguished into four forms based on the morphologic characteristics. Genetic similarity and heterogeneity were analyzed among the four forms by random amplified polymorphic DNA (RAPD) technique using 24 10-nucleotide-long primers. Of these primers, 22 primers produced well-identifiable RAPD band patterns. Significant differences in RAPD band patterns were revealed among the four forms. A total of 198 polymorphic fragments were scored from 22 primers, and they are specific for one form, shared by two or three forms. Several primers, such as S451, S453, S463, S464, S470, S473, and S474, produced abundant band patterns and provided sufficient information for reliable discrimination of the four forms. The average genetic distances and phylogenetic relationships were calculated and analyzed according to the distinguishable fragments. The data indicate that pen shells of form G and form Y are similar not only among individuals within the same form, but also between individuals from the two forms, and that shells of form T and form S are highly divergent. The constructed phylogenetic tree matches the average genetic distances. Three clusters were clearly distinguishable, in which two were corresponding to form S and form T respectively and one included forms G and Y. This study will be benefit to further studies on the taxonomy and selective breeding of Pinnid species. It is suggested that the four forms of pen shell should be categorized to at least two species taxonomically.

KEY WORDS: RAPD marker, genetic polymorphism, taxonomy, *Atrina pectinata*

INTRODUCTION

Marine shells of the family Pinnidae are a popular food source and of high commercial value in a number of Asia-Pacific countries. In China, there are a number of Pinnid species that are presently categorized into three subgenera. The pen shell, *Atrina pectinata* Linnaeus, is the most commercially prominence of these species and is the only Pinnid species found in both northern and southern China waters (Wang 1997). In the South China Sea, including Baibu Gulf, *A. pectinata* shows considerable morphologic variation, which has produced considerable taxonomic confusion for more than 40 y (Wang 1964, 1997, Liang et al. 1986, Bernard et al. 1993). In an attempt to characterize its diversity and analyze its population structure, two methods, morphologic comparison and isoenzyme electrophoresis, have been used. These studies have revealed significant variations in not only exterior shell character and size of posterior adductor muscle (Yu et al. 2000), but also in the isozyme electrophoretograms (Wang et al. 2000).

According to their morphologic characteristics, especially the traits of exterior shell, *Atrina pectinata* in the South China Sea, can be divided into four forms: "green pen shell" (form G), "yellow pen shell" (form Y), "thorny pen shell" (form T), and "scabrous pen shell" (form S), respectively (Fig. 1). In areas such as the Leizhou Peninsula, collections of shells from four sites have shown that the four forms are sympatric. In collections from Donghai Island and Wailuo, all four forms occur in similar numbers, whereas at Shatian and Qintou, forms G and Y are most common, with only a few individuals of form T or S (Fig. 2; Yu's personal observation). Electrophoretic comparisons of isozymes from different tissues have indicated that there are differences in the isozyme phenotypes among the four forms, which are consistent with the morphologic forms. This electrophoretic analysis has

shown that forms G and Y are analogous, while form S differs markedly (Yu et al., 2000; Wang et al., 2000).

The random amplified polymorphic DNA (RAPD) technique is a rapid and sensitive polymerase chain reaction (PCR)-based method (Williams et al., 1990) that has been widely used in polymorphism analysis for genetic structures. The RAPD technique had been shown to be a powerful tool for discrimination of different aquatic species or subspecies and for genetic analysis of phylogenetic relationships among strains or populations (Zhou & Gui 2000a, 2000b, 2002, Gui, 2003). In marine bivalves, RAPD techniques have been used to analyze genetic variation in oysters (Liu et al. 1998, Liu & Dai 1998), mussels (Kimura et al. 1997) and scallops (Patwary 1994), and proved an appropriate tool at molecular level for identifying divergence between populations or sibling species.

In this study, the RAPD technique was used for analyzing genetic diversity in the four forms of *Atrina pectinata*. We sought to reveal whether the four forms of pen shell distinguished morphologically could also be categorized by RAPD analysis. One of aims was to select suitable strains for farming because several traits differ among the four forms, such as the comparative size of adductor muscle, which is related to consumer popularity and market price in China. Another main aim is to provide more convincing evidence for the taxonomic categorization of the different forms of pen shell.

METHODS

Source of Samples

A total of 85 individuals of the four forms that caught from coast waters of Zhanjiang and nearby areas, in southern China (Fig. 2), were used for morphologic comparison. Because preliminary experiments demonstrated that most individuals in same forms produced basically identical RAPD band patterns, only eight adult individuals selected from each form were used to analyze genetic similarity and heterogeneity and to seek the specific markers for discriminating different forms.

Figure 1. Four forms of *Atrina pectinata* distributed in Southern China Sea. Type G: green pen shell; type T: thorny pen shell; type Y: yellow pen shell; type S: scabrous pen shell.

Morphologic Comparison

Morphologic comparison was performed by observing the shell exterior and partially anatomic characters, such as the shell surface status, the radial sculpture situation, scale, the color of pallial organ and kidney, the ratio of shell height/shell breadth, and so on.

DNA Extraction

Total genomic DNA was isolated from ovarian tissue using standard phenol-chloroform extraction procedures (Sambrook et al., 1989). Briefly, about 1.5 g of tissue from each sample was homogenized into 15 mL of homogenized buffer (10 mM Tris-HCl, pH 8, 75 mM NaCl, 5 mM EDTA, 0.5% SDS) at 4°C. RNase was added and the suspension was incubated for 1 h at 37°C. 100 $\mu\text{g}\cdot\text{mL}^{-1}$ of proteinase K was then added and the suspension was again incubated for 2 h at 55°C. Proteins and other impurities were removed by extraction with phenol:chloroform:isoamyl alcohol (25:24:1). The DNA was precipitated with 2 volumes of cold ethanol, 1/10 volume 3 M NaAc and resuspended in TE buffer (10 mM Tris-HCl, 1 mM EDTA, pH 8). After quality and concentration, samples were determined by agarose electrophoresis as described (Zhou et al. 1998), the DNA samples were stored at -80°C .

RAPD-PCR

Because RAPD analysis is particularly sensitive to the concentration of DNA, magnesium, primer, and Taq DNA polymerase, the optimal reaction conditions must be determined before study (Black 1993, Williams et al. 1993). In our system for RAPD amplification of the four forms of pen shells, we adopted the condi-

tions at the raised annealing temperature of 39°C, which is higher than in other systems and amplified abundant and reproducible band patterns.

Amplification reactions were performed in volume of 25 μL containing approximately 20 ng of template DNA, 15 ng of primer, 0.5 units of Taq polymerase (Promega), 0.1 μM of each dNTP, and 10 \times Buffer for Taq polymerase (Promega) as described by Zhou et al. (1998). RAPD primers were obtained from Shanghai Biotech (Shanghai, China). A total of 24 10-nucleotide-long primers were used. PCR amplifications were performed in a Perkin-Elmer DNA GeneAmp PCR System 9600, with an initial denaturation at 94°C for 4 min, followed by 38 cycles of 1 min at 94°C, 1 s at 39°C, 50 s at 72°C, and a final extension at 72°C for 7 min. Amplification products were separated by electrophoresis on 1% agarose gels. Sizes in kilo base (kb) pairs were inferred by comparisons with a Lambda DNA/ *EcoRI* + *HindIII* marker (Sino-America Bio). Gels were stained by ethidium bromide and recorded on a white/ultraviolet transilluminator with computer (UVP, Ultra-Violet Products).

RAPD Data Analysis

Twenty-two primers were found to produce well-amplified and reproducible electrophoretic band patterns. Using these informative bands, all individuals from every form were evaluated by RAPDistance 1.04 program in computer. For each individual, about 104 distinguishable fragments, including universal and specific, were scored with data coded as a vector of 1 or 0 representing band presence or absence respectively. Distance matrices among the 46 individuals of four forms were estimated based Apostol (1993). Phylogenetic trees showing the hierarchical structures of RAPD pattern affinities among individuals and forms were constructed from the distance matrices by NJTREE analysis, as implemented in the program of RAPDistance 1.04 (Apostol 1993).

RESULTS

Morphologic Difference Among the Four Forms

The data about morphologic traits of the four forms were summarized in Table 1. As shown in Table 1, their morphologic traits can be easily discriminated among the four different forms, especially in the aspects of exterior shell character and the ratio of shell height/shell breadth. Form Y is most analogous to typical parameters of *Atrina pectinata* described by Wang (1997).

Similarity and Heterogeneity of RAPD Band Patterns Within and Between the Four Forms

The similarity and heterogeneity of RAPD band patterns within and between the four forms were screened using 24 primers, of which, 22 primers reproducibly produced well-identifiable RAPD band patterns (1 to 12 bands ranging from about 0.2 to 2.5 kb; Table 2). No anyone of the RAPD band patterns produced by the 22 primers was identical in all of the four forms. As shown in Figure 3, there are significant differences in RAPD band patterns among the four forms. Some characteristic RAPD band patterns for the different form were produced, and only a few polymorphic bands were observed among individuals in each form. In comparison with form T and form S, forms G and Y exhibit more similarity in RAPD band patterns (Fig. 3).

two or three forms. Several primers, such as S451, S453, S463, S464, S470, S473, and S474, produced abundant band patterns and provided sufficient information for reliable discrimination of the four forms analyzed. As shown in Figure 3, primer S451 amplified one 2.2-kb fragment shared by all forms, one 0.5-kb fragment specific for form S, one 0.2 fragment specific for form T and another 0.8-kb fragment shared by forms G and Y. Primer S453 gave rise to two bands of 0.9 kb and 1.4 kb shared by forms G, Y and T, one 0.3-kb band shared by forms G and Y, and another 0.4-kb band specific for form S. Primer S463 generated four fragments in all individual of forms G and Y, two fragments in all form S individuals, five fragments in form T. Primer S470 yielded two fragments of 0.7-kb and 1.2-kb band specific for form S, three fragments of 0.2 kb, 0.8 kb and 1.0 kb specific for form T, and one 0.6-kb fragment shared by forms S, G and Y. Most of the polymorphic fragments can be used as specific RAPD markers for discriminating the four different forms in *Atrina pectinata*.

Average Genetic Distances and Phylogenetic Relationships

The average genetic distances and phylogenetic relationships were calculated and analyzed according to the total of 4788 distinguishable fragments obtained from the all RAPD band patterns. As shown in Table 3, the average genetic distances among individuals in form G (0.1362 ± 0.02487) and form Y (0.1195 ± 0.02622) are lower than that in form T (0.1769 ± 0.05324) and form S (0.1896 ± 0.02758), and the average genetic distance (0.1447 ± 0.02309) between form G and form Y is basically equal to that among individuals in the form G or Y. In contrast, the average genetic distances between form S and form T, between form S and form G, between form S and Y, between form T and form G, and between form T and form Y are very much high, and range from 0.4229 ± 0.02535 to 0.4888 ± 0.02227 (Table 3). These data indicate that the form G and form Y are closely related not only among individuals within the same form, but also between individuals from the two forms, and form T and form S are highly divergent.

The phylogenetic tree of the 46 individuals from the four forms was obtained by NJTREE analysis in the RAPDistance program, as shown in Figure 4. Three clusters were clearly distinguishable, in which two were corresponding to form S and form T respectively and one included forms G and Y. Any specimen was first clustered with other individuals from the same form. Apparently, forms G and Y are most closely related, while the most divergence occurs between forms S and G or Y. The constructed phylogenetic tree (Fig. 4) matches the average genetic distances among the four forms (Table 3).

DISCUSSION

In traditional mollusk taxonomy, characteristic shell features and organ structure are the main basis for categorizing different species and subspecies. But, some of these features are malleable and vary in accordance with environmental conditions. These various features and structures resulted in considerable confusion and controversy among taxonomists. For *Atrina pectinata*, debate as to whether the present species should be divided to two or more species or subspecies have lasted for years. In China, the four forms of pen shell were generally grouped to one species, *A. pectinata* (Wang 1997). In past decade, some new biochemical and molecular biologic methods, such as allozyme electrophoresis,

Figure 3. Electrophoretogram of three typical RAPD band patterns produced by S451, S453, and S470 primers, indicating some specific or shared bands for one, two, or three forms.

mitochondrial DNA restriction mapping and RAPD polymorphic analysis, have been applied in comparison of genetic variation and taxonomic studies.

Thorp (1982) deduced from studies of classification of populations that the genetic similarity (I) below 0.85 between two populations should be on inter-species level. I value between 0.2 and

0.8 on level of inter-species in same genus, between 0.8 and 0.97 on level of populations of same species. In other words, while the genetic distance (1 - I) over 0.20 between two populations, the two populations should be categorized into different species.

In several mollusk species, the genetic distances (D) were estimated from data of isozyme electrophoresis and morphologic

TABLE 3.
Average genetic distances among the four forms of *Atrina pectinata*.

Form	G	Y	T	S
G	0.1362 ± 0.02487			
Y	0.1447 ± 0.02309	0.1195 ± 0.02622		
T	0.4319 ± 0.02469	0.4229 ± 0.02535	0.1769 ± 0.05324	
S	0.4888 ± 0.02227	0.4686 ± 0.02178	0.4458 ± 0.02881	0.1896 ± 0.02758

differences. Krause et al. (1994) surveyed the genetic variation among three geographic populations of calico scallops *Argopecten gibbus*. The genetic distance between populations was between 0.009 and 0.070. The nearer genetic distances were agreed with lower level of morphologic variation, both on the level of geographic population within same species. Three mussel species (*Mytilus edulis*, *M. galloprovincialis*, and *M. trossulus*) were ana-

lyzed by Skibinski et al. (1980), Grant and Cherry (1985), and Vainola and Hvilson (1991), the Nei's (1972) distance (D) among these three mussels was in the range of 0.16 to 0.28. Gosling (1992) regarded the above three mussels as a subspecies status. The swan mussel *Anodonta woodiana* living in same pond in Japan has been known to exhibit two forms. Tabe et al. (1994) made clear that D distance between the two forms was 0.707 and no

Figure 4. The phylogenetic trees of 46 individuals from four forms of pen shell by NJTREE analysis, as implemented by RAPD Distance, version 1.04

hybrid was observed, they suggested that these two forms should be regarded as distinct species. Buroker (1979a, 1979b) studied the intraspecific and interspecific genetic divergence of the family Ostreidae, and found that the D value of 0.0118–0.0408 was on the level of intraspecific populations, whereas above 0.165 was beyond sibling species. The reports on RAPD analysis in mollusc were not as much as that of isozyme electrophoresis. Patwary (1994) first used RAPD technique in bivalve mollusc for analyzing genetic divergence in scallop *Placopecten magellanicus* Gmelin and distinguished different allele frequencies in different populations. Wilding et al. (1998) analyzed genetic differentiation of morphotypes of periwinkle *Littorina saxatilis* from two locations of England. They considered the diverse RAPD patterns as evidence of separate gene pools. Liu et al. (1998a, 1998b) analyzed RAPD polymorphism of oyster species in northern China, and found that genetic distances between three species *Crassostrea talienwhanensis*, *C. plicatula* and *C. gigas* were among 0.333–0.400, whereas the intraspecific distances between four geographic populations of *C. talienwhanensis* were below 0.2004. These researches were almost conformed to inferences about D distance suggested by Thorp (1982)

In Pinnadea species, very few data about their genetic background could be obtained. Koji Yokogawa (1996) had examined and calculated genetic divergence of nonscaly and scaly pen shell *Atrina pectinata* distributing in partial Japanese marine region by isozyme electrophoresis. Based on the high D value (0.469) and low frequency of hybrids, Koji Yokogawa (1996) suggested that the two forms would be taxonomically distinguished. In this study, we demonstrated that different forms of *Atrina pectinata* amplified diverse RAPD band patterns, and that specific markers created by some primers can be efficiently used to discriminate the four different forms of pen shell. Twenty-two primers produced a total of

4,788 distinguishable bands from 46 individuals of the four forms, and 87 markers specific for some forms (Table 2). The dendrogram and average genetic distances clearly indicate phylogenetic relationships among the four forms. Among the four different forms, form G was clustered together with form Y, and their average genetic distance is the smallest (≤ 0.15), even smaller than the intra-form distance of form T (≥ 0.17) and S (≥ 0.18). The most divergence occurred between form S and forms G (or Y), their genetic distance is more than 0.48. The data imply that form G has a very high genetic homogeneity to form Y, and form S is distinctly contrasted to form G (or Y) in the genetic background. It should be reliable to say that the pen shell, previously regarded as one species, *Atrina pectinata*, should be a conspecific complex composed of at least two species. Form G and Y are same species, and form S is another species different from them. Form T remains undecided, and it might belong to either group or be the third species or subspecies.

Of course, RAPD data in our study could only be a proof for classification of these four forms, further investigations should be conducted to provide more and convincing evidences. Two experiments are going to be carried out: 1) by crossing between the form G and form S, the most genetically distant forms, to observe the survival status of their hybrids, 2) by cloning and sequencing specific RAPD fragments to develop diagnostic PCR SCAR primers (Zhou et al. 2001) for reliable discrimination of the four forms. These new evidences will be benefit to further reclassification of *A. pectinata*.

REPRODUCTIVE PATTERN OF THE BLOOD ARK, *ANADARA OVALIS* FROM THE NORTHEAST COAST OF FLORIDA

ALAN J. POWER,¹ JOSE NUNEZ,² MARCY MITCHELL,¹ RANDAL L. WALKER¹ AND LESLIE STURMER²
¹Shellfish Research Laboratory, University of Georgia Marine Extension Service, Savannah, Georgia 31411-1011; ²Whitney Laboratory, University of Florida, St. Augustine, Florida 32080

ABSTRACT In blood arks, the sexes are separate; however, a low incidence of hermaphrodites was observed in the current study (2.17%). Males occurred more frequently than females (m/f = 2.68). Ripe arks were present year round outside of the period from August to November 2002. A bimodal reproductive pattern was apparent with a peak in gonadal development during the late spring-early summer months (45% ripe in May), followed by a quiescent period in the late summer-fall, and followed in turn by a minor peak during the winter months (21% ripe in December). Spawning was apparent in all months with the exception of September, and individuals in this phase were most numerous in June (50%) and July (64.29%). Dribble spawning is likely used as a strategy to extend its spawning period and increase its reproductive success. A low incidence (3.33%) of parasitic infection by digenetic trematodes resulting in castration was also noted. The implications of these findings on the aquaculture potential of this species are discussed.

KEY WORDS: ark, gametogenesis, reproduction, sex ratio, spawning, *Anadara ovalis*

INTRODUCTION

Several ark species (*Scapharca*, *Arca*, and *Anadara* spp.) form the basis of economically significant molluscan fisheries and extensive culture operations (Baqueiro et al. 1982, Baqueiro 1989, Broom 1985, MacKenzie 2001, Manzi & Castagna 1989, Nie 1990, Umezawa 1992). A member of the ark shell family Arcidae, the blood ark, *Anadara ovalis* (Bruguière 1789) occurs from Cape Cod, Massachusetts, to the West Indies and Brazil, at depths ranging from the low-tide line to >3 m (Abbott 1974, Anderson et al. 1984, Rehder 1981, Walker & Gates 2001). The species favors sandy deposits (Alexander 1993) and salinities above 15 ppt (Chanley & Andrews 1971). With a short lifespan (<5 y), early maturity (10–12 mm/–8 mo), rapid growth rates, and established markets in the Northeast, this bivalve has shown tremendous potential as an aquaculture species to diversify hard clam operations in Southeastern coastal waters (McGraw et al. 1996, McGraw et al. 1998, Power & Walker 2001, Power & Walker 2002, Walker 1998).

In Florida, *A. ovalis* occurs mainly on the eastern coast whereas the related ponderous ark (*Noetia ponderosa*, Say 1822) also inhabits the Gulf Coast. A concerted effort is currently underway among researchers and extension agents on both coasts of Florida and on the Georgia coast to investigate the hatchery-rearing protocol for both species. A systematic histologic examination of the gonads is a critical step providing information on the gametogenic cycle and sex ratios. By knowing the natural gametogenic cycle of a species, hatchery operators will know when to collect brood stock in the field while they are at their optimum ripe stage prior to their spawning. Histologic analysis of gonadal tissue also allows hatchery operators to know if animals from the natural population can be spawned more than once per year. This can save time and money in conditioning the bivalves to an optimum ripe stage within the hatchery. Knowledge of the sex ratio of a species determines the number of individuals that must be held for conditioning and spawning.

The reproductive biology of the blood ark has not previously been investigated for populations anywhere in Florida. In Virginia, blood arks are reported to spawn in the summer months when water temperatures reach above 17°C (Chanley & Andrews 1971, McGraw et al. 1998). In Georgia, blood arks spawn earlier, from late spring through summer (Power & Walker, 2002). In

general, spawning periods and gametogenesis in marine bivalves start earlier and last longer in southern geographical areas than in northern ones (Eversole 1989, Thompson et al. 1996), and therefore the gametogenic cycles from Florida can be expected to be unique and clearly warrant investigation.

MATERIALS AND METHODS

Blood arks were collected from harvested clam bags during processing at certified shellfish wholesalers (Sturmer et al. 1995) and subsequently replanted in a commercial clam lease on the Matanzas River near "Marineland" south of St. Augustine, Florida, for holding and continued growout over the annual study period. The salinity and temperature of the river were monitored at the Whitney Laboratory floating dock every 30 min using a YSI 6600 data sonde.

Each month between May 2002 and April 2003, approximately 30 specimens were shipped to the Shellfish Research Laboratory in Savannah, Georgia. Immediately upon arrival, each individual was measured for shell length, width, height, and total weight (McGraw et al. 1996), and a mid-lateral gonadal sample (ca. 1 cm²) was dissected for histologic analysis. Notes on the gonad color were recorded. Gonadal tissue was fixed in Davidson's solution, refrigerated for 48 h, washed with 50% ethanol, and preserved in 70% ethanol until processing. We processed tissues according to procedures outlined in Howard and Smith (1983). The examination of prepared gonadal slides was conducted with a Zeiss Standard 20 microscope (20×). Each animal was sexed and assigned to a developmental stage as described by Walker and Heffernan (1994) and Spruck et al. (1994). A staging criteria of 0 to 5 was used for early active (EA = 3), late active (LA = 4), ripe (R = 5), partially spawned (PS = 2), spent (SP = 1), and inactive (IA = 0). The determination of monthly gonadal index (G.I.) values was obtained by averaging the number of specimens ascribed to each category score. We tested sex ratios against a 1:1 ratio with chi-square (χ^2) statistics (Elliott 1977).

RESULTS

Monthly mean water temperature and salinity data for the Matanzas River are shown in Figure 1. Water temperatures ranged from 12 to 28°C between the winter and summer months. Salinities showed less of an annual pattern, and values ranged from 22

Figure 1. The mean monthly water temperature and salinity of the Matanzas River, Florida, from May 2002 to April 2003.

Figure 2. The mean monthly shell length, shell width, shell height (mm ± standard error) and total wet weight (g ± standard error) of the blood arks, *Anadara ovalis*, sacrificed for the histologic analysis between May 2002 and April 2003.

Figure 3. A histologic section through the gonad of a hermaphroditic blood ark, *A. ovalis*, showing ripe oocytes and spermatozoa.

to 33 ppt. Figure 2 displays the mean size parameters (length, width, height, and weight) of monthly samples. The average length of blood arks from all samples combined was 41.34 mm (± 0.22 SE). The largest and smallest ark observed in terms of shell length, width, height, and weight measured 52.59 mm, 39.58 mm, 41.15 mm, 58.90 g, and 29.50 mm, 21.00 mm, 88.10 mm, and 13.10 g, respectively.

Of the 323 arks examined histologically, 73 (22.60%) were sexually indeterminate, 177 (54.80%) were male, 66 (20.43%)

were female, and 7 (2.17%) were hermaphroditic (Fig. 3). Figure 4 reveals the size distribution of arks according to these categories. Both male and female arks were most abundant in the 42-mm shell-length class and represented in similar proportions in the smaller and larger size classes. Hermaphroditic arks occurred between 38 and 48 mm. Males dominated in all monthly samples with the exception of September 2002, where there were two with four females; however, a large percentage (75%) of individuals in this sample did not display any gonadal activity and therefore were sexually indeterminate (Fig. 5). The χ^2 test revealed that the overall male/female ratio of 2.68 was significantly different from parity ($\chi^2 = 7.89$; $P < 0.01$). Histologic examination and visual observations of the gonads revealed that all orange-red colored gonads were females whereas those showing white coloration were typically males.

Ripe arks were present in most samples, with the exception of those taken from August to November 2002 (Fig. 6). Similarly, partially spawned individuals were observed throughout the year with the notable exception of September 2002, when all gonads were completely spent. While an extended spawning period from May to September was observed, a bimodal annual pattern was apparent in the G.I. plot. Gonadal development peaked during the late spring-early summer months (45% ripe in May), followed by a quiescent period in the late summer-fall, and followed in turn by a minor peak during the winter months (21% ripe in December). The largest coordinated spawning effort was in June and July, where 50% and 64.2% of individuals had partially spawned gonads. Partially spawned gonads often had smaller areas of ripe and late active follicles.

A low incidence (3.33%) of parasitic infection by digenetic trematodes resulting in castration was also noted. No seasonal

Figure 4. The frequency size distribution (2-mm shell length classes) of blood arks, *A. ovalis*, identified as male, female, hermaphroditic, or indeterminate during the course of the annual study.

Figure 5. Variations in the female:male ratio of blood arks, *A. ovalis*, in monthly samples taken from St. Augustine, Florida, between May 2002 and April 2003. Shown also are the percentage of individuals each month labeled as male, female, hermaphrodite, and indeterminate.

pattern in parasitic infection was evident, with one specimen being infected in the months of May, June, July, September, November, December 2001, and March 2002, and two specimens in the months of January and February 2002. Spearman's rank correlation coefficients detected a significant correlation between mean water salinity levels and the mean monthly G.I. ($r_s = 0.67$, $t = 2.07$, $df = 11$, $\alpha = 0.05$).

DISCUSSION

In Long Island Sound, New York, the transverse ark, *Anadara transversa* (Say, 1822), is reported to spawn between May and August (Loosanoff & Davis 1963). Further south in the Chesapeake, this species spawns from May to September (Chanley & Andrews 1971). In Georgia, a more extended period is observed for the transverse ark with major spawning occurring between April and July, and some spawning also occurring in the winter months of December and January (Walker & Power, 2003). Similarly, for the related blood arks, a spawning period from May to September has been identified for the Chesapeake area (McGraw et al. 1998) whereas a more extended period over most of the year but peaking in the summer has been reported for Georgia (Power & Walker 2002). Further south in Costa Rica, ripe *Anadara tuberculosa* (Sowerby, 1883) are present throughout the year with a peak in spawning activity between May and September (Cruz 1984a). Additionally, *Anadara similis* (Adams, 1852) and *Anadara grandis* (Broderip & Sowerby, 1829) from these waters are also ripe year round but have peaks during the winter months (Cruz 1984b, Cruz 1987). From this synopsis, it would appear that the spawning pattern of the Arcidae family becomes less confined to a single narrow season with decreasing latitude and the associ-

ated reduction in temporal fluctuations in temperature and coastal phytoplankton abundance. Based on the current study, it is apparent that blood arks from the northeast of Florida can also remain in the ripe and spawning phases for most of the year and that salinity may be a controlling factor in the gametogenic cycle.

A prolonged spawning period has distinct advantages and disadvantages for producing the species in a commercial hatchery. During the microscopic analysis of histologic slides, partially spawned gonads with patches of ripe and late active follicles were frequently observed. It is therefore likely that this species achieves a long spawning season by maturing different sections of its gonad at different times. This would give rise to a "dribble" spawning reproductive strategy, wherein gametes are not released synchronously as a massive event within the population, but instead small amounts are periodically released over an extended time period. In a hatchery, such a strategy would reduce the number of viable gametes available through a single induced spawning effort. As a result, either more individuals or repeated spawning attempts during several weeks and months might be necessary to generate sufficient numbers of larvae.

A clear advantage is that broodstock can be obtained and spawned almost anytime outside of the fall months, allowing for multiple spawnings per year. Of course, the optimal time for spawning is the early summer based on the percentage of individuals synchronously in the desirable late active, ripe, and partially spent gonadal stages (>80%). During the winter reproductive peak, less than 50% of individuals display gonads at these stages. Therefore, spawning in the early summer months would reduce the number of individuals required for conditioning.

A reduction in the number of broodstock required is important

Figure 6. The relative frequency (percentage) of each gonadal developmental phase (EA = early active, LA = late active, R = ripe, PS = partially spawned, and S = spent) of *A. ovalis* between May 2002 and April 2003. Monthly gonadal index (G.I.) values are also shown and were determined by averaging the number of specimens ascribed to each category score (EA = 3, LA = 4, R = 5, PS = 2, SP = 1).

because only one in three to four blood arks are likely to be female (M:F = 2.68:1.00). The male domination reported here is in general agreement with previously reported sex ratios for the species in Virginia (1.98:1.00 M:F; McGraw et al. 1998) and in Georgia (2.44:1.00 M:F; Power & Walker 2002). This is, however, the highest male to female ratio recorded for a member of the Arcidae family (see review in Power & Walker 2002). Hermaphroditism was observed for the species in the current study for the first time, albeit at a low incidence. One individual displayed a large area of mature oocytes sandwiched between two similarly sized areas of spermatozoa whereas the other six had only a few follicles of the extra gamete. Hermaphroditism is rare in the whole Arcidae family. A low incidence has been reported for *Anadara granosa* (0.003%) and *Anadara senilis* (0.004%) Broom (1983, 1985, respectively). It has been suggested that these might be protandric hermaphrodites. Males typically dominate protandric bivalve species in the first year whereas older age classes are generally equal. However, the specimens examined in the current study were generally of the larger and older size classes and were still dominated by males.

Males and females were also represented in similar ratios throughout the entire shell length size distribution analyzed (i.e., 30–52 mm). In addition, one male ark maintained in a conditioning tank with 39 others (both sexes) at the Whitney Laboratory was induced to spawn female gametes 2 mo after having last released spermatozoa. This does not support a protandric hermaphroditic life cycle, and the observed phenomenon cannot be explained.

ACKNOWLEDGMENTS

This work was supported by congressional funds from the State of Florida (Grant No. USDA Grant # 2002-34453-11946). The authors thank Mr. Phil Cubbedge for providing and holding the arks on his lease and Mr. Micah Alo for his assistance in the field. Thanks to Ms. Rebecca Green, Ms. Dodie Thompson, and Ms. Mary Sweeney-Reeves for dissecting the samples and to Ms. Lisa Calvo and Prof. Gene Bureson at the Virginia Institute of Marine Science Department of Environmental and Aquatic Animal Health for diagnosing the trematode infections.

HISTOLOGICAL STUDIES ON HERMAPHRODITISM, GAMETOGENESIS AND CYCLIC CHANGES IN THE STRUCTURES OF MARSUPIAL GILLS OF THE INTRODUCED ASIATIC CLAM, *CORBICULA FLUMINEA*, AND THE KOREAN CLAM, *CORBICULA LEANA*

GAB-MAN PARK^{1*} AND EE-YUNG CHUNG²

¹Department of Parasitology, Kwandong University College of Medicine, Gangneung, Gangwon-do 210-701, Korea; ²School of Marine Life Science, College of Marine Science and Technology, Kunsan National University, Kunsan, Chollabuk-do 573-701, Korea

ABSTRACT The marsh clams, *Corbicula fluminea* and *Corbicula leana*, are functional hermaphrodites. They usually appear to be surrounded by numerous spermatozoa in the hermaphroditic follicles. In both species, the follicular ganglia (consisting of the neuronal fiber and neuronal soma-like cells at its periphery) are associated with neurosecretion and the differentiation of complex innervated nerve structures during spermatogenesis and are widely distributed in the follicles in the ripe and spawning stage. *Corbicula fluminea* and *C. leana* have two pairs of gills, with the inner-demibranchs acting mainly as marsupia. The non-marsupial demibranchs are not separated, but in the marsupial demibranchs, cyclic changes in the structures of the inner-demibranchs of the gills appear, with the depletion of ripe eggs during incubatory periods and the production of mature and ripe eggs during nonincubatory periods. The reproduction of triploid *C. fluminea* and *C. leana* may occur by parthenogenesis without self-fertilization (or cross-fertilization) by eggs and sperm. The DNA contents of the somatic (gill) and gamete (spermatozoa) cells of *C. fluminea* are the same. Because reproduction is parthenogenetic, numerous spermatozoa may participate in the activation of the mature eggs and egg cleavage, as a stimulus only for parthenogenesis in the same hermaphroditic follicle or the gonophore.

KEY WORDS: *Corbicula fluminea*, *Corbicula leana*, gametogenesis, hermaphroditism, Korea, North American

INTRODUCTION

The freshwater clams *Corbicula fluminea* and *Corbicula leana* are hermaphrodites that brood their larvae in the inner-demibranchs (Britton and Morton 1982, Miyazaki 1936). Okamoto and Arimoto (1986) suggested that *C. leana* reproduce by gynogenesis. *Corbicula fluminea* and *C. leana*, on the basis of chromosomal and karyological studies have been reported as being triploid (Okamoto and Arimoto 1986, Park et al. 2000). The triploid condition may closely be related to hermaphroditism.

The Korean clam, *C. leana*, is one of the commercially important edible clams. However, the North American *C. fluminea* was introduced from Asia in the 1900s and is now widely distributed throughout the United States (Britton and Morton 1982, McMahon 1982), where it has become a biofouling pest (Mattice 1979, McMahon 1977). There have been a few previous studies of the reproduction of the *Corbicula* species (Kennedy and van Huekelem 1985, Kraemer 1978, Kraemer 1984, Kraemer et al. 1986, Morton 1982, Williams and McMahon 1986). In addition, gametogenesis and the corresponding morphologic changes in the inner-demibranchs have not been examined. Finally, there is the question whether the reproduction of the two triploid *Corbicula* species involves self-fertilization, cross-fertilization, or parthenogenesis.

The purposes of this study were to understand functional hermaphroditism, gametogenesis, the cyclic changes in the structures of the inner-demibranchs, and the duration of the pediveligers released from the parent clams. The DNA content of the spermatozoa and gill tissues of *C. fluminea* were also compared.

MATERIALS AND METHODS

Among *Corbicula* species used for the current study, a total of 366 North American *C. fluminea* specimens collected from the Bethel Lake Dam, Pitman, Gloucester County, New Jersey, between July 1995 and December 1996 were examined shortly after

being identified. Three hundred fifty-two specimens of *C. leana* were collected from the Keum River, Korea, between February 2000 and December 2001. The 30 to 40 individuals were collected on a monthly basis for this study.

The live clams were transported to the laboratory of the Museum of Zoology, University of Michigan, and the Department of Parasitology, Kwandong University, and the shell lengths and heights measured using Vernier calipers and their total weight determined using a balance. Histologic preparations were made to study the sexuality, gametogenesis, and morphologic changes in the structures of the demibranchs by light microscopy. The visceral mass and the gill tissues were subjected to standard histologic procedures (dehydrated in alcohol and embedded in paraffin), and 5–7- μ m sections prepared using a rotary microtome. The sections were then mounted onto glass slides, stained with Hansen's hematoxylin-0.5% eosin and Mallory's triple stain, and observed using light microscopy.

To compare the relative DNA content of the spermatozoa and gill tissue of *C. fluminea*, cells were isolated on a glass slide by cutting small pieces of gonad and gill tissues in distilled water and air-drying it before fixing with 70% ethanol. The spermatozoa and gill cells from one individual were placed on the slide. The cells were stained with DNA-specific dyes PI (propidium iodide) and DAPI (4',6-diamidino-2-phenylindole), and the relative DNA content (fluorescence intensity) per cell estimated by microfluorometry, as in Komaru et al. (1988). The DNA content was assayed at least three times at each of three different concentrations of spermatozoa and gill cells. Twelve individuals were used for these assays. The spermatozoa could easily be distinguished from the other spermatogenic cells due to their elongate and curved morphology.

RESULTS

Sexuality and Functional Hermaphroditism

The gonad of the freshwater clams *C. fluminea* and *C. leana* is located between the digestive diverticula and the outer fibromus-

cular layers, which are compacted by the fibrous connective tissues and muscle fibers. As the gonad matures, it extends to the lowest part of the muscular layers, around the foot. Both *Corbicula* species were hermaphrodites (monoecious), and gonad consisted of a number of oogenic, spermatogenic, or hermaphroditic follicles. Both female and male germ cells were present in the oogenic, spermatogenic, or hermaphroditic follicles (Figs. 1–20). More specifically, triploid *C. fluminea* and *C. leana* showed hermaphroditism, and a group of the ovotestis (Figs. 6, 16, and 20), or intrafollicular embryos, usually appeared to be surrounded by numerous spermatozoa in the hermaphroditic follicles during egg cleavage (Figs. 8 and 20). The functional hermaphroditism was shown in the hermaphroditic follicles.

Gametogenesis

The oogenesis of the two *Corbicula* species occurred in the oogenic or hermaphroditic follicles between the digestive and the outer fibromuscular layers and was divided into five stages: oogonial, previtellogenic oocyte, vitellogenic oocyte, and mature oocyte stages. Also, spermatogenesis occurred in the spermatogenic or hermaphroditic follicles, between the digestive diverticula and the outer fibromuscular layers, and was divided into five

stages: spermatogonial, primary spermatocyte, secondary spermatocyte, spermatid, and spermatozoon stages. The characteristics of gametogenesis of the two *Corbicula* species are as follows.

Corbicula fluminea

This species is a hermaphrodite. The gonad consisted of a number of oogenic (Figs. 1, 2, 3, and 4), spermatogenic (Figs. 2, 3, 5, and 7), or hermaphroditic (Figs. 6 and 8) follicles.

Oogenesis Oogenesis occurred in the oogenic and hermaphroditic follicles. The oogenic and hermaphroditic follicles located near the outer muscular layer begin to develop toward the visceral mass. A number of oogonia appeared along the follicular walls (16–18 μm in diameter) and had a round nucleus containing a nucleolus in its center. One nucleolus in the nucleus was distinct in appearance, though the cytoplasm of the oogonium was very poor stained. At this time, a number of undifferentiated mesenchymal tissues and eosinophilic cells were both located near the follicle walls (Fig. 1). The oogonium developed into the previtellogenic oocyte. The previtellogenic oocyte (30–36 μm in diameter) had a round nucleus containing one or more small eosinophilic nucleoli along the nuclear envelope, and the cytoplasm begin to grow in volume. Undifferentiated mesenchymal and eosinophilic granular cells were abundant on the follicular wall. There were widely distributed interfollicular connective tissues near the follicles (Fig. 2). Early vitellogenic oocytes grew to 130–140 μm in diameter and became eosinophilic oval or pentagonal oocytes in the oogenic or hermaphroditic follicles (Fig. 3). Mature oocytes (about 150–170 μm) had one large nucleolus, 3–4 small nucleoli in the nucleus, and numerous yolk granules in the cytoplasm. At this stage, the vitelline envelope of the mature oocyte was surrounded with a gelatinous substance (Fig. 4).

Spermatogenesis Spermatogenesis occurred between the digestive diverticula and the outer fibromuscular layers. The spermatogonia were 8–9 μm in diameter and contained a large oval nucleus located in the wall of the spermatogenic or hermaphroditic follicles. Undifferentiated mesenchymal cells and eosinophilic cells were located near the spermatogonia and spermatocytes (Fig. 5). The spermatocytes developed into the spermatids. At this time, the spermatids in the center of lumina of the hermaphroditic follicles were occupied with a few oocytes; the interfollicular connective tissues were also widely occupied (Fig. 6). At the early differentiation stage of the spermatid, the shape of the nucleus changed gradually and became slightly elongated and narrow. After spermatogenesis (transformation of the spermatid into the spermatozoon), a number of the spermatozoa formed needle-shaped sperm clusters in the male follicles (Fig. 7). The spermatozoon was approximately 12–13 μm in length, and the sperm head was approximately 1.0 μm in width.

In the partially spawned follicle, an embryo uncleaving, surrounded by a number of sperm, appeared in the hermaphroditic follicle (Figs. 8 and 9), indicating that *C. fluminea* is a functional hermaphrodite. Male reproductive tissue was less common than female tissue. At this time, the gonoduct was located near the spermatogenic follicle, and the follicular ganglia (consisting of the neuronal fiber and neuronal soma-like cells at its periphery), associated with neurosecretion and the differentiation of complex innervated nerve structures during spermatogenesis, were widely distributed in the follicles during the ripe and spawning stages (Figs. 10 and 11).

Cyclic Changes in Structures of the Inner-Demibranchs A pair of the inner-demibranchs acted mainly as marsupium. Incubated ripe eggs and D-shaped veliger larvae were rarely found within a pair of the outer-demibranchs. The non-marsupial demibranchs were not separated and had no secondary septa and tripartite marsupial structure. In this case, the outer-membranes of the demibranchs were slightly thicker (Fig. 12A). In the case of the marsupial demibranchs, the morphologic and structural changes in the inner-demibranchs of the gills showed a distinct seasonal alternation or periodicity in relation to depletion of ripe eggs during the incubatory periods, with the production of mature and ripe eggs during the nonincubatory periods. In the late nonincubatory period, during gametogenesis, or before depletion of the ripe gametes, the tripartite marsupial structures completely disappeared, and the epithelial cells lining the inner-lamellar spaces of the inner-demibranchs became gradually thicker (Fig. 12B). During the early incubatory period of the inner-demibranchs (removal of ripe gametes or early developing embryos from the gametogenic follicles to the gills), a number of ripe eggs and D-shaped veliger larvae were filled in thickened inter-lamellar spaces of the inner-demibranchs (Fig. 12C). In the late incubatory period (gonads in

Figures 10 and 11. *Corbicula fluminea*: "Follicular ganglion" section from anterior region of visceral mass. Many neuronal-like soma(s) at the periphery of the "ganglion" and its location within a well-developed spermatogenic follicle.

the partially spawned stage), a number of incubated D-shaped veliger or pediveliger larvae were found in the inter-lamellar spaces of the inner-demibranchs. Thereafter, as the marsupial demibranchs began to be separated by the secondary septa, the secondary septa produce secondary water tubes (Fig. 12D). Consequently, in the early nonincubatory period, the tripartite marsupial organization that was formed by the secondary septa and water tubes appeared in the inner-demibranchs (Fig. 12E). At this time, the inter-lamellar spaces of the tripartite marsupial demibranchs were vacant, as a number of the D-shaped veligers in the marsupial gills were released.

Some characteristics of the relationships between the structural changes of the inner-demibranchs in the marsupial gills and gametogenesis in the gonads were found: most gonads became degenerate and appeared to be depleted of female and male gametes during the incubatory and larval release periods. Therefore, inhibition of gametogenesis might occur during the incubatory periods (especially during the mid-summer and early autumn incubation and D-shaped veliger larvae release).

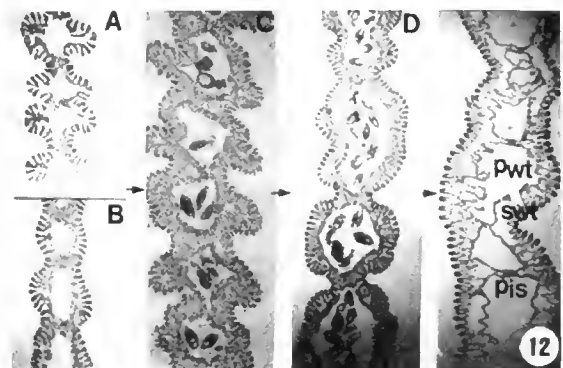

Figure 12. *Corbicula fluminea*: Photomicrographs of cyclic changes in structures of the inner-demibranch during gametogenic cycle. (A) Cross section of the outer-demibranch, (B) cross section of the inner-demibranch, (C) a number of ripe eggs and D-shaped veliger larvae fill the thick inter-lamellar spaces of the inner-demibranch, (D) marsupial demibranch shown separated by the secondary septa, (E) in the early nonincubatory period, the tripartite marsupial organization is formed by the secondary septa and secondary water tube. (Abbreviations: pis, primary interlamellar septum; pwt, primary water tube; swt, secondary water tube.)

Corbicula leana

This species is a triploid (Okamoto and Arimoto 1986) and a hermaphrodite. The gonad consisted of a number of the oogenic (Figs. 13 and 15) and spermatogenic (Figs. 17, 18, and 19) or hermaphroditic (Fig. 20) follicles. The spermatogenic and oogenic or hermaphroditic follicles were distributed among the interfollicular connective tissues. The characteristics of gametogenesis of this species were as follows.

Oogenesis Oogenesis occurred in the oogenic follicles. Many oogonia (15–18 μm) propagated along the follicle wall near the mesenchymal tissues. The oogonia had one large basophilic nucleus and light basophilic cytoplasm (Fig. 13). The oogonia developed into the previtellogenic oocytes; at the beginning of cytoplasmic growth, each oocyte (ranging in diameter from 20 to 40 μm) had an egg-stalk and was attached to the follicle walls of the oogenic follicle near the spermatogenic follicle, which contained a number of spermatids. In the early vitellogenic oocytes (50–70 μm), the cytoplasm was markedly stained with eosin (Fig. 14). The vitellogenic oocytes (80–100 μm) and the late vitellogenic oocyte (110–130 μm) were located in the center of the lumina of the follicle, and numerous eosinophilic yolk granules in the cytoplasm were filled (Fig. 15). The mature oocytes (more than 140–160 μm) had 4–7 nucleoli in the nucleus, and many yolk

granules in the cytoplasm were filled. The mature oocytes were surrounded by a gelatinous substance. Several mature oocytes were found in the lumen of the hermaphroditic follicles and contained numerous spermatozoa (Fig. 16).

Spermatogenesis The testes were composed of a number of spermatogenic and hermaphroditic follicles, including oogenic tissues. The spermatogonia, which were distributed along the follicular wall, were approximately 9 μm in diameter and had relatively little cytoplasm. The spermatogonia developed into the primary spermatocytes, and the primary spermatocytes developed into the secondary spermatocytes. The chromatin in the nucleus of the spermatocyte became gradually more concentrated, while the volume of the cytoplasm of the secondary spermatocyte gradually became smaller. The secondary spermatocytes developed into spermatids, which were darkly stained with hematoxylin, and distributed in the center of the lumina of the spermatogenic follicle. Stratified layers of the spermatogonia, spermatocytes, and spermatids formed in the male follicle (Fig. 17). The spermatids developed into spermatozoa in the spermatogenic or hermaphroditic follicles, containing a few ovotestis on the oogenic tissue (Fig. 18). A number of needle-shaped sperm clusters, formed by numerous spermatozoa, filled the spermatid follicle. The spermatozoon was approximately 12 μm in length, and the head was approximately 1.2 μm in width. During spermatogenesis, follicular ganglia (consisting of neuronal fiber and neuronal soma-like cells) were widely distributed in the spermatogenic follicle, but gradually disappeared (Fig. 19). In the spawning period, the embryo-like body, surrounded by a number of sperm clusters, appeared in the hermaphroditic follicle (Fig. 20).

Relative DNA Content of Spermatozoa and Somatic (Gill) Cells

In *C. fluminea*, the relative content of the DNA in the spermatozoa was identical to that in the gill cells (Fig. 21). Komaru et al. (1997) reported that *C. leana* is a triploidy species, and from microfluorometric analyses, the sperm and somatic cells were shown to have the same DNA content. They suggested that meiosis I or II may be abortive in spermatogenesis, with only one equal division resulting in nonreductional spermatozoa.

DISCUSSION

In general, hermaphroditism is seen more frequently in freshwater than marine mollusks (Van der Schalie 1970). *Corbicula* species can be categorized into three major groups, based on their reproductive characters and ecologies (Miyazaki 1936). Species belonging to Group 1 are monoecious, viviparous, and incubatory. They have nonswimming planktonic veliger larvae and live in freshwater. The species belonging to Group 2 are dioecious, oviparous, nonincubatory, and also live in freshwater regions. The species belonging to Group 3 are dioecious and oviparous. They do not incubate their young, have free-swimming planktotrophic larvae, and live in brackish waters. In this study, *C. fluminea* and *C. leana* were confirmed to be hermaphroditic species (Group 1). According to our histologic observation, the two *Corbicula* species were hermaphroditic throughout their lifetime, with no sex reversal. According to Coe's report (Coe 1943), cited by Heard (1975), hermaphroditic conditions in pelecypods were divided into four categories, according to the sequence of reproductive events: (1) functional hermaphroditism (eggs and sperm produced simultaneously), which can be subdivided into two groups: (i) normal

(typically in monoecious species) and (ii) accidental or development (typically in dioecious species); (2) consecutive sexuality (single sex-reversal, usually protandrous); (3) rhythmical sexuality (>1 sex-reversal, usually protandrous); and (4) alternative sexuality (adults function seasonally as separate sexes). Monoecious species can be grouped as male (predominance of testicular tissue; animal not gravid) and female (ovarian tissue slightly or greatly exceeding quantity of testicular tissue; animal may become gravid) hermaphrodites. In the current study, *C. leana* and *C. fluminea* were found to be functional hermaphrodites.

Kraemer and Lott (1977) reported that although the largest *Corbicula* species exceeded 20 mm in size, they consistently showed a clear predominance of ovarian over testicular development. *Corbicula fluminea* had greater volumes of oogenic than spermatogenic tissue. The oogenic follicles were larger, with a clear predominance and well-developed oocytes. In particular, in the case of triploid species, this phenomenon might occur because of parthenogenetic reproduction. The results of this study on *Corbicula* species support the previous findings by Kraemer and Lott (1977). Okamoto and Arimoto (1986) proposed that triploid species might closely be related to hermaphroditism. With reference to hermaphroditism and fertilization, there have been some reports that *C. fluminea* carry out both self-fertilization (Kraemer 1978, Kraemer et al. 1986) and cross-fertilization (Kraemer 1978). In this study, some intrafollicular embryos were found in the course

of egg cleavage in the hermaphroditic follicles of *C. fluminea* (Fig. 8). At a glance, some intermingling of a number of spermatozoa and a few oocytes in the same follicle suggest that self-fertilization may occur in the hermaphroditic follicle. However *C. fluminea* is a triploid species (Park et al. 2000), and its DNA content in the nucleus of the somatic cell (gill) is the same as that in the gamete cell (sperm). Komaru et al. (1997) reported that *C. fluminea* was a diploid species and produced nonreductional spermatozoa. If *C. fluminea* sexually reproduces itself, the DNA content in the nucleus of the somatic cell, and the number of the homozygote genes, would increase in volume and chromosome numbers, respectively, due to egg and sperm fertilization. Therefore, reproduction of this species may occur by parthenogenesis, without self- or cross-fertilization of eggs and sperm. The DNA contents in the nuclei of the somatic and gamete cells of *C. fluminea* were the same. In the case of parthenogenesis, it is assumed that numerous spermatozoa may participate in activation of the mature eggs, and the eggs cleavage as a stimulus only for parthenogenesis in the same hermaphroditic follicle or the gonopore. Komaru et al. (1998) reported that cytologic observations and DNA microfluorometry of the hermaphrodite freshwater triploid clam *C. leana* revealed androgenetic development.

Bivalves have two pairs of gills. In the case of *Corbicula* species, two pairs of gills act as the marsupia, but the pair of inner-demibranchs mainly play an important role as the marsupia; in general, a pair of the outer-demibranchs occasionally act as the marsupia. Differences in the structural and morphologic changes between the non-marsupial and marsupial demibranchs are very clear. Heard (1975) described that in *Anodonta*, the non-marsupial demibranchs did not form the secondary septa, and a comparatively large number of filaments were distributed between the inner membranes of the primary septa, whereas marsupial demibranchs were divided by the secondary septa that produced the secondary water tubes, resulting in tripartite marsupial organization. However, Kwon and Park (1985) stated that after the glochidia had been released, the secondary water tube was continuously present in *Lanceolaria acrorhyncha*. In this study, the patterns reported by Heard (1975) were found in *C. fluminea*. In the late nonincubatory period, during gametogenesis or before spawning, the structures of the tripartite marsupial inner-

Figure 21. *Corbicula leana*: Fluorescence histograms of the spermatozoa and gill cells of *C. fluminea*, stained with PI (propidium iodide) and DAPI (4',6-diamidino-2-phenylindole dihydrochloride).

demibranchs disappeared, while the inner-membranes of the marsupial gills were vacant and became very thick. In the early incubatory period, during movement of ripe gametes or early developing embryos in the gametogenic follicles to inner-demibranchs, a number of ripe eggs or D-shaped veliger larvae filled the thickened epithelial cells lining the inter-lamellar spaces of the inner-demibranchs. In the late incubatory period, the late pediveligers or straight-hinged juveniles (approximately 230–240 μm in size), which had grown in the marsupial gills for approximately 7–10 days, began to shed into the environmental water. At this time, the primary water tubes began to separate, and the secondary water septa formed in the marsupial gills. Consequently, in the early nonincubatory period, the tripartite marsupial organization appeared in the inner-demibranchs of the gills. In our histologic study, the two *Corbicula* species were found to be hermaphrodites, with specified demibranchs of the gills. Particularly, gametogen-

esis inhibition occurred in the gametogenic follicles during the gills incubatory period whereas active gametogenesis occurred during the nonincubatory period. The structural hypertrophy of the epithelial cells lining the inter-lamellar spaces was especially changed in relation to the nonincubatory and incubatory periods of the inner-demibranchs. Therefore, the results of this study suggest that the larvae may receive nourishment from the hypertrophied epithelial cells that line the inter-lamellar spaces of the inner-demibranchs of the adult clam. Thus, the morphologic changes in the structure of the marsupial gills, during the incubatory and nonincubatory periods, with gametogenesis and spawning patterns, may occur cyclically or have a certain short-term periodicity. In conclusion, *C. fluminea* and *C. leana* are functional hermaphrodites, with the spermatozoa in the triploidy *Corbicula* species showing an identical DNA content to the somatic tissue of the parent.

FEEDING BY LARVAE OF THE MUSSEL *MYTILUS GALLOPROVINCIALIS* ON RED-TIDE DINOFLAGELLATES

HAE JIN JEONG,^{1*} JAE YOON SONG,² CHANG HOON LEE,³ AND SEONG TAEK KIM²

¹School of Earth and Environmental Science, College of Natural Sciences, Seoul National University, Seoul 151-747; ²Department of Oceanography, College of Ocean Science and Technology, Kunsan National University, Kunsan 573-701; ³Red Tide Research Center, Kunsan National University, Kunsan 573-701, Republic of Korea

ABSTRACT To investigate feeding by the larvae of the mussel *Mytilus galloprovincialis* on red-tide dinoflagellates, we measured grazing rates of *M. galloprovincialis* larvae as a function of larval age and prey concentration when feeding on several species of the red-tide dinoflagellates *Alexandrium affine*, *Cochlodinium polykrikoides*, *Lingulodinium polyedrum*, *Prorocentrum minimum*, *Prorocentrum micans*, and *Scrippsiella trochoidea*, as well as the flagellate *Isochrus galbana* as a control species. The larvae were able to ingest all dinoflagellates offered in the current study; however, first feeding of the larvae on each species of the dinoflagellates occurred 9–13 days after fertilization, whereas that for *I. galbana* occurred after 5 days. Ingestion rates of the larvae on unialgal diets of the dinoflagellates and *I. galbana* increased with increasing larval age up to 17–21 days, but were saturated or showed a continuous increase thereafter. Ingestion rates of 25-day-old larvae feeding on unialgal diets of the dinoflagellates increased rapidly with increasing prey concentration up to 1000–2200 ng C mL⁻¹, but were saturated at higher prey concentrations. The harmful alga *C. polykrikoides*, which has been responsible for great losses in the aquaculture industry, was the optimal prey. Maximum ingestion and clearance rates of the larvae on these dinoflagellates were 14–69 ng C predator⁻¹ day⁻¹ and 1.5–11.4 μ L predator⁻¹ h⁻¹, respectively. *M. galloprovincialis* larvae, one component of microzooplankters, exhibited higher maximum ingestion and clearance rates than previously reported for other microzooplankters, such as *Fragilidium* cf. *mexicanum* (mixotrophic dinoflagellate), *Protopridinium* cf. *divergens*, *Polykrikos kofoidii* (heterotrophic dinoflagellates), or *Tiarina fusus* (small ciliate), but lower rates than *Strombidinopsis* sp. and *Favella* sp. (large ciliates). The results of the current study suggest that dinoflagellates sometimes can be primary prey for the *Mytilus* larvae, and the grazers compete with other microzooplankters for dinoflagellate prey. Also, red-tide dinoflagellates can be used for culturing the *Mytilus* larvae as prey in the aquaculture industry.

KEY WORDS: benthic–pelagic interaction, benthos, bivalve; HAB, mollusca, plankton, *Mytilus*

INTRODUCTION

Bivalves and dinoflagellates are major components of benthos and plankton in marine environments, respectively (Ruppert & Barnes 1994, Steidinger & Tangen 1997). Red tides and/or harmful algal blooms dominated by phototrophic dinoflagellates often have caused large-scale mortality of adult bivalves (e.g., ECOHAB 1995). As a consequence, there have been many studies on interactions between adult bivalves and red-tide dinoflagellates (Widows et al. 1979, Nielsen & Stromgren 1991, Shumway & Cembella 1993, Shumway et al. 1997, Matsuyama et al. 1997, Bricelj & Shumway 1998). Bivalve larvae spend a certain period after hatching as plankton and need to feed on planktonic prey. Red-tide dinoflagellates often dominate phytoplankton assemblages in coastal waters. Thus, there is a high possibility that bivalve larvae frequently encounter red-tide dinoflagellates. While there are some studies on the grazing by bivalve larvae on microflagellates and/or diatoms in the laboratory (Bayne 1965, Riisgård et al. 1980, Sprung 1984a, Sprung 1984b, Leonardos & Lucas 2000), there are a few studies on the interactions between bivalve larvae and red-tide dinoflagellates (Wikfors & Smolowitz 1995, Matsuyama et al. 2001); no data are available for bivalve larvae grazing rates as a function of red-tide dinoflagellate concentration and first feeding age for prey species.

Among bivalves, the genus *Mytilus* has a cosmopolitan distribution (e.g., Seed 1976). Some species are commercially important and cultivated at high densities in many countries (Hickman 1992). *Mytilus galloprovincialis* is a common bivalve in Europe (Moroño et al. 1998, Tubaro et al. 1998), Asia (Matsuyama et al. 1997,

NFRDI 1999), and Oceania (Gardner 2002) and is spreading to other areas as an invasive species (McQuaid & Phillips 2000).

To investigate interactions between bivalve larvae and red-tide dinoflagellates, we established cultures of *M. galloprovincialis* larvae and conducted experiments to examine their functional response when fed a variety of red-tide dinoflagellates. Our goal was to explore the predator–prey relationship between *M. galloprovincialis* larvae and red-tide dinoflagellates by determining the larval ingestion and clearance rates as functions of prey concentration and larval age.

The maximum ingestion and clearance rates of *M. galloprovincialis* larvae on unialgal diets of red-tide dinoflagellates were compared with those of other microzooplankters (heterotrophic dinoflagellates, and ciliates), which also are potential competitors, when feeding on the same prey species. Results of the current study provide a basis for understanding the interactions between bivalve larvae and red-tide dinoflagellates.

MATERIALS AND METHODS

Culture of Phytoplankton Prey

The dinoflagellates (Table 1) which have formed red tides in many coastal waters (Eppley & Harrison 1975, Jeong 1995, Ismael 2003) were grown at 19 °C in enriched 1/2 seawater media (Guillard & Ryther 1962) without silicate, under continuous illumination of 100 μ E m⁻² s⁻¹ provided by cool white fluorescent light. Only cultures in the exponential growth phase detected by cell count were used for the feeding experiments. Carbon contents for red-tide dinoflagellates were estimated from the volume of cells in batch cultures according to Strathmann (Strathmann 1967).

Species of red-tide dinoflagellate prey and a flagellate *Isochrysis galbana* used in the current study, listed in order of cell volume.*

Species	ESD + Standard Error (μm)	Approximate Volume (μm^3)
<i>Isochrysis galbana</i> (IGKC99)	4.8 \pm 0.2	57
<i>Prorocentrum minimum</i> (PMJH99)	12.9 \pm 3.6	1100
<i>Cochlodinium polykrikoides</i> (CPKS00)	23.2 \pm 3.1	6600
<i>Alexandrium affine</i> (AAJM00)	24.0 \pm 1.1	7200
<i>Scrippsiella trochoidea</i> (STKP99)	25.1 \pm 2.8	8300
<i>Prorocentrum micans</i> (PMCJH99)	26.0 \pm 2.3	9200
<i>Lingulodinium polyedrum</i> (LPSD95)	37.9 \pm 4.5	28,500

* Mean equivalent spherical diameter (ESD) was measured by the PAMAS-SVSS particle counter. Volume was calculated according to the equation: Volume = $4/3 \pi (\text{ESD}/2)^3$. The number of cells measured, n , was >2000 .

Preparation of *M. galloprovincialis* Larvae

Approximately 300 adults of the blue mussel *M. galloprovincialis* were collected from an aquafarm off Yeosu, Korea, in March 2001 when the seawater temperature was 12 °C and the salinity was 33.4 psu. The shell length of the mussels ranged from 45 to 65 mm and gonads of most individuals were at late active or ripe stages. The mussels were transported to the laboratory within 6 h after collection and then acclimated to an experimental temperature (15 °C) for two months. During acclimation, the mussels were maintained in two 200-L aquariums where seawater freshly filtered through 5 μm GF/F filters and air from an air pump were supplied. The microflagellate *Isochrysis galbana* (final concentration = approximately 10^3 cells mL^{-1}) was provided as prey every day. The mussels were observed daily to check their condition, and dead mussels were removed immediately after they were found.

Spawning of the mussels was induced from May to June when natural spawning usually occurs in the Korean coastal waters. Approximately 10 individuals were used for each spawning period. Before spawning, the shell surface of the mussels was scraped to remove epibionts and rinsed with freshly filtered seawater. To

induce spawning, the mussels were exposed to air for 1 h, put back into a 10-L aquarium filled with freshly filtered seawater, and then the water temperature was increased gradually to 25 °C. Most of these mussels released sperm and eggs within 30 min after the water temperature reached 25 °C. As soon as any male first released sperm, the other males were removed to avoid possible polyspermy. One hour after spawning, all mussels were removed, and then aliquots of the water in the aquarium were taken to determine the fertilization rate. During the current study, we induced spawning 10 times, and the fertilization rates were always $>95\%$. The mean diameter of the fertilized eggs was approximately 60 μm . The egg suspension was passed through a 100- μm mesh screen to remove fecal material and other large particles, and a 35- μm mesh screen was used to collect fertilized eggs without excessive numbers of sperm and smaller eggs. The eggs were rinsed three times with 5- μm filtered and autoclaved seawater and were then incubated in a 20-L aquarium at 15 °C in darkness without aeration. After 1-day incubation, most eggs had developed to the trochophore larval stage. From the first day after fertilization, *Isochrysis galbana* (final concentration = approximately 5×10^3 cells mL^{-1}) was provided to larvae as prey every day. Incubation water was wholly renewed every day.

Ingestion Rates as a Function of Larval Age

Experiments 1 to 7 were designed to measure ingestion and clearance rates of *M. galloprovincialis* larvae as a function of the larval age (elapsed time after fertilization), when feeding on unialgal diets of 6 red-tide dinoflagellate species and *Isochrysis galbana* as a control species (Table 2). Feeding experiments were conducted when larvae were 1, 5, 9, 13, 17, 21, and 25 days old, because settlement of the larvae had started when they were 27 days old.

One day before these experiments were conducted, cultures of *M. galloprovincialis* larvae unfed (for the 1-day-old larvae) or growing on *Isochrysis galbana* (for the other aged larvae) were sieved through meshes of 80–150 μm , and the larvae retained were transferred into 1-L polycarbonate (PC) bottles. The bottles were filled to capacity with filtered seawater and placed on plankton wheels rotating at 0.9 rpm and incubated at 15 °C under continuous

TABLE 2.

illumination of $50 \mu\text{E m}^{-2} \text{s}^{-1}$ from cool white fluorescent light. One day later, prey inside the stomach of the larvae was almost digested and indiscernible by microscope examination. The abundance of *M. galloprovincialis* larvae was determined by enumerating larvae in three 1-mL Sedgwick-Rafter counting chambers (hereafter SRCs).

Initial densities of *M. galloprovincialis* larvae and target prey were established using an autopipette to deliver predetermined volumes of known densities to the bottles. Triplicate 270-mL PC experiment bottles (mixtures of predator and prey) and triplicate control bottles (prey only) were set up at each predator-prey combination. Triplicate control bottles containing only *M. galloprovincialis* larvae also were established. Thirty milliliters of f/2 medium were added to each bottle. Each bottle then was filled to capacity with freshly filtered seawater and capped. The bottles were placed on plankton wheels under the environmental conditions described above. To determine actual predator and prey densities at the beginning of the experiment, and after 24, 48, and 72 h incubation, 10-mL aliquots were removed from each bottle and fixed with 5% Lugol's solution, and all larvae and all or >200 prey cells in three 1-mL SRCs were enumerated. Prior to taking subsamples, the condition of *M. galloprovincialis* larvae and prey was assessed by looking through the surface of each capped bottle using a dissecting microscope. The bottles were filled again to capacity with freshly filtered seawater, capped, and placed on plankton wheels as described above. Dilution of the cultures associated with refilling the bottles was considered in calculating ingestion rates.

Ingestion and clearance rates of *M. galloprovincialis* larvae on RTDs were calculated using the equations of Frost (1972). The incubation time for calculating ingestion and clearance rates was 48 h.

To examine the occurrence of ingestion by *M. galloprovincialis* larvae on each prey species, 2-mL aliquots from each experimental and control bottle, preserved with Lugol's solution after 48 h incubation, were transferred into wells of 12-well plate chambers. Subsequently, 0.3 mL thiosulfate ($\text{Na}_2\text{S}_2\text{O}_3$) of a 10^5 mg L^{-1} con-

Figure 1. *Mytilus galloprovincialis* larva fed (A) and unfed (B) red-tide dinoflagellates. An undigested *Prorocentrum micans* cell (arrow) from the crushed stomach of a larva (C). Scale bars are 50 μm in (A & B) and 20 μm in (C).

Figure 2. Shell length of *Mytilus galloprovincialis* larvae used for Experiments 1 to 7 as a function of larval age. Symbols represent treatment means ± 1 SE. $n = 37\text{--}403$ for each larval age.

Figure 3. Ingestion (A) and clearance rates (B) of *Mytilus galloprovincialis* larvae on *Prorocentrum minimum* as a function of larval age. Symbols represent treatment means \pm 1 SE.

centration was added into each well to decolorize. One day later, the stomachs of the larvae were examined at 40–200 \times using Olympus compound and dissecting microscopes, and photographs were taken. Also, to find any undigested prey cells inside the stomachs of the larvae, approximately 20 *M. galloprovincialis* larvae fed on *Prorocentrum micans* were rinsed and carefully crushed using a very thin needle. We chose *P. micans* because it has an easily discernible shape. Photographs of the contents from the stomach were taken.

The shell lengths of *M. galloprovincialis* larvae at the beginning of each experiment and after 48 h incubation were measured using an image analyzing system; each individual larva was observed at a magnification of 20 \times , and its image was recorded using a Toshiba Model IK-642K CCD camera attached to a stereo-zoom microscope (Nikon, SMZ-U). Measurements of the shell length (the distance between the anterior and posterior ends of a shell) were conducted using the UTHSCSA Image Tool program. The shell lengths of 30 larvae at each age were measured.

Ingestion Rates as a Function of Prey Concentration

Experiments 8 to 13 were designed to measure ingestion and clearance rates of 25-day-old *M. galloprovincialis* larvae, as a

function of prey concentration, when feeding on unialgal diets of the red-tide dinoflagellates (Table 2).

The procedures for setting-up experiments, measuring predator and prey densities, and calculating ingestion and clearance rates were the same as described above, except that 80-mL PC bottles were used, 10 mL of f/2 medium were added into each bottle, and 5-mL aliquots were removed from each bottle and fixed with 5% Lugol's solution.

Ingestion rate data were fitted to a Michaelis–Menten equation:

$$IR = I_{\max}(x)/[K_{IR} + (x)] \quad (1)$$

where I_{\max} = the maximum ingestion rate (cells predator⁻¹ day⁻¹ or ng C predator⁻¹ day⁻¹); x = prey concentration (cells mL⁻¹ or ng C mL⁻¹), and K_{IR} = the prey concentration sustaining $\frac{1}{2} I_{\max}$.

RESULTS

Feeding and Shell Length of *Mytilus* Larvae

M. galloprovincialis larvae were able to ingest all red-tide dinoflagellates offered in the current study. The larvae fed on RTD in feeding currents produced by the ciliated velum. The stomach areas of *M. galloprovincialis* fed red-tide dinoflagellates were 20–

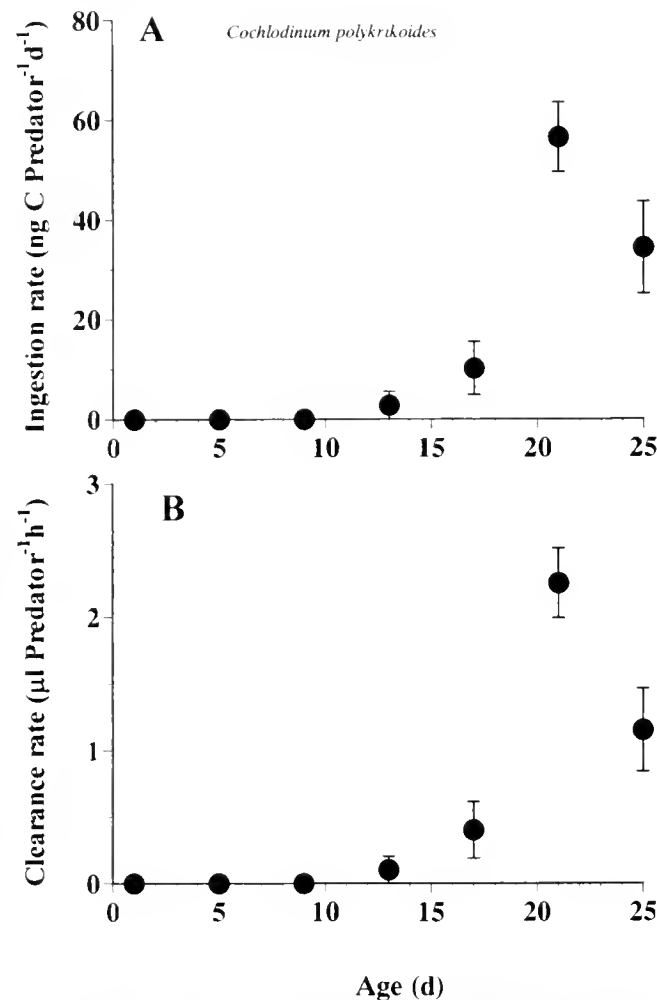

Figure 4. Ingestion (A) and clearance rates (B) of *Mytilus galloprovincialis* larvae on *Cochlodinium polykrikoides* as a function of larval age. Symbols represent treatment means \pm 1 SE.

Figure 5. Ingestion (A) and clearance rates (B) of *Mytilus galloprovincialis* larvae on *Alexandrium affine* as a function of larval age. Symbols represent treatment means \pm 1 SE.

30% larger than those starved in the control bottles, and the color of the stomachs of fed larvae became dark brown, whereas that of unfed larvae was almost transparent (Figs. 1A and 1B). Undigested *Prorocentrum micans* cells from the crushed stomachs of the larvae also ascertained the ingestion of the prey species (Fig. 1C).

With increasing larval age (elapsed time after fertilization), the mean shell length of *M. galloprovincialis* larvae almost linearly increased from 69 to 204 μm (Fig. 2).

Ingestion and Clearance Rates as a Function of Larval Age

The first feeding by *M. galloprovincialis* larvae on each red-tide dinoflagellate species occurred when the larvae were approximately 9–13 days old (Figs. 3–8); whereas that for *Isochrysis galbana* occurred at the larval age of 5 days (Fig. 9).

The ingestion rates of *M. galloprovincialis* larvae on *P. minimum* were undetectable when the larvae were 1–5 days old. However, they increased to 6–14 ng C predator⁻¹ day⁻¹ at the larval age of 9–21 days and reached 26 at 25 days (Fig. 3A). The clearance rates were 0.2–0.5 $\mu\text{L predator}^{-1} \text{h}^{-1}$ at the age of 9–21 days and reached 0.9 at 25 days (Fig. 3B).

The ingestion rates of *M. galloprovincialis* larvae on *Cochlodinium polykrikoides* were undetectable or very low when the larvae were 1–13 days old, but they rapidly increased to 34–56 ng C predator⁻¹ day⁻¹ at the larval age of 21–25 days (Fig. 4A). The clearance rates also were undetectable or very low at the larval age of 1–13 days, but increased to 1.3–2.3 $\mu\text{L predator}^{-1} \text{h}^{-1}$ at the larval age of 21–25 days (Fig. 4B).

The ingestion rates of *M. galloprovincialis* larvae on *Alexandrium affine* were undetectable or very low when the larvae were 1–17 days old, but they rapidly increased to 19 ng C predator⁻¹ day⁻¹ at the age of 25 days (Fig. 5A). The clearance rates also were undetectable or very low at the larval age of 1–17 days, but increased to 0.8 $\mu\text{L predator}^{-1} \text{h}^{-1}$ at the larval age of 25 days (Fig. 5B).

The ingestion rates of *M. galloprovincialis* larvae on *Scrippsiella trochoidea* were undetectable or very low when the larvae were 1–13 days old, but they increased rapidly to 19–20 ng C predator⁻¹ day⁻¹ at the age of 21–25 days (Fig. 6A). The clearance rates also were undetectable or very low at the larval age of 1–13 days, but increased to 0.3–0.7 $\mu\text{L predator}^{-1} \text{h}^{-1}$ at the larval age of 21–25 days (Fig. 6B).

Figure 6. Ingestion (A) and clearance rates (B) of *Mytilus galloprovincialis* larvae on *Scrippsiella trochoidea* as a function of larval age. Symbols represent treatment means \pm 1 SE.

Figure 7. Ingestion (A) and clearance rates (B) of *Mytilus galloprovincialis* larvae on *Prorocentrum micans* as a function of larval age. Symbols represent treatment means \pm 1 SE.

The ingestion rates of *M. galloprovincialis* larvae on *Prorocentrum micans* were undetectable when the larvae were 1–9 days old, but they increased rapidly to 27–32 ng C predator⁻¹ day⁻¹ at the age of 17–25 days (Fig. 7A). The clearance rates were also undetectable or very low at the larval age of 1–9 days, but increased to 0.8–1.2 μ L predator⁻¹ h⁻¹ at the larval age of 17–25 days (Fig. 7B).

The ingestion rates of *M. galloprovincialis* larvae on *Lingulodinium polyedrum* were undetectable when the larvae were 1–9 days old, but they were 10–11 ng C predator⁻¹ day⁻¹ at the age of 13–21 days (Fig. 8A). The rates reached a maximum of 27 ng C predator⁻¹ day⁻¹ at the age of 25 days. The clearance rates were also undetectable when the larvae were 1–9 days old, but they were 0.1–0.4 μ L predator⁻¹ h⁻¹ at the age of 13–21 days (Fig. 8B). The rate reached a maximum of 1.1 μ L predator⁻¹ h⁻¹ at the age of 25 days.

The ingestion rates of *M. galloprovincialis* larvae on *Isochrysis galbana* were undetectable when the larvae were 1 day old, but they were 19–32 ng C predator⁻¹ day⁻¹ at the age of 5–17 days (Fig. 9A). The rates reached maximum of 111 ng C predator⁻¹ day⁻¹ at the age of 21 days. The clearance rates were also undetectable when the larvae were 1 day old, but they were 1.0–1.7 μ L predat-

tor⁻¹ h⁻¹ at the age of 5–17 days (Fig. 9B). The rate reached a maximum of 7.8 μ L predator⁻¹ h⁻¹ at the age of 25 days.

No dead *M. galloprovincialis* larvae were found upon examination with a dissecting microscope prior to taking subsamples in these experiments.

Ingestion and Clearance Rates as a Function of Prey Concentration

In Experiments 8 to 13, the ingestion rates of 25-day-old *M. galloprovincialis* larvae on unialgal diets of *P. minimum*, *C. polykrikoides*, *A. affine*, *S. trochoidea*, *P. micans*, and *L. polyedrum* increased rapidly with increasing prey concentration up to 1000–2200 ng C mL⁻¹, but were almost saturated at higher prey concentration (Figs. 10–15). When the data were fitted to Eq. 1, the maximum ingestion rates of *M. galloprovincialis* larvae in ng C predator⁻¹ day⁻¹ and (prey cells predator⁻¹ day⁻¹) were 69 (99) for *C. polykrikoides*, 56 (60) for *P. micans*, 45 (18) for *L. polyedrum*, 26 (173) for *P. minimum*, 21 (25) for *S. trochoidea*, and 14 (18) for *A. affine* (Table 3). Maximum clearance rates of *M. galloprovincialis* larvae were 11.4 μ L predator⁻¹ h⁻¹ for *L. polyedrum*, 8.4 for *P. micans*, 3.8 for *A. affine*, 3.5 for *S. trochoidea*, 2.8 for *C. polykrikoides*, and 1.5 for *P. minimum*.

Figure 9. Ingestion (A) and clearance rates (B) of *Mytilus galloprovincialis* larvae on *Isochrysis galbana* as a function of larval age. Symbols represent treatment means \pm 1 SE.

DISCUSSION

Prey Species and Feeding Rates as a Function of Larval Age

There has been no report on the feeding by larvae in the genus *Mytilus* on red-tide dinoflagellates. *M. galloprovincialis* larvae were able to feed on all red-tide dinoflagellate prey offered in the current study. Thus, *M. galloprovincialis* larvae have diverse prey species. In the phylum mollusca, larvae of the oyster *Crassostrea virginica* have been shown to feed on the dinoflagellate *P. minimum* (Wikfors & Smolowitz, 1995), and larvae of the gastropod *Philine aperta* feed on the dinoflagellates *Heterocapsa triquetra* and *Scrippsiella faroense* (Hansen 1991). Further studies on feeding by other molluscan larvae on diverse red-tide dinoflagellates are necessary to better understand their interactions.

Mytilus edulis larvae have been known to ingest particles of 1–9 μ m (Riisgård et al. 1980, Sprung 1984b). However, *M. galloprovincialis* larvae are able to ingest red-tide dinoflagellates whose ESDs are 12–38 μ m (Table 1). The change in color of the stomachs of the larvae and undigested prey cells found in the crushed stomachs indicated their ingestion (Fig. 1). The mouths of the larvae may be very flexible for ingesting large prey cells or different species in the genus *Mytilus* may have different prey size limitations.

Figure 10. Ingestion rates of 25-day-old *Mytilus galloprovincialis* larvae on *Prorocentrum minimum* as a function of mean prey concentration. Symbols represent treatment means \pm 1 SE. The curves are fitted by a Michaelis-Menten equation (Eq. 1) using all treatments (see Table 3).

The first feeding by *M. galloprovincialis* larvae on each red-tide dinoflagellate species occurred when the larvae were approximately 9–13 days old (Figs. 3–8), whereas that for *I. galbana* occurred at the larval age of 5 days (Fig. 9). Much larger size of red-tide dinoflagellates might delay the larval first feeding.

Figure 11. Ingestion rates of 25-day-old *Mytilus galloprovincialis* larvae on *Cochlodinium polykrikoides* as a function of mean prey concentration. Symbols represent treatment means \pm 1 SE. The curves are fitted as in Fig. 10.

Figure 12. Ingestion rates of 25-day-old *Mytilus galloprovincialis* larvae on *Alexandrium affine* as a function of mean prey concentration. Symbols represent treatment means \pm 1 SE. The curves are fitted as in Fig. 10.

The ingestion and clearance rates of *M. galloprovincialis* larvae on red-tide dinoflagellates at the larval ages of 21–25 days (14–56 ng C predator⁻¹ day⁻¹ and 0.5–2.3 μ L predator⁻¹ h⁻¹, respectively) measured in Experiments 1 to 7 were lower than those on *I. galbana* (107–111 ng C predator⁻¹ day⁻¹ and 6.5–7.8 μ L predator⁻¹ h⁻¹) (Figs. 3–9). Therefore, red-tide dinoflagellates are less preferred prey for *M. galloprovincialis* larvae than *I. galbana*.

Figure 13. Ingestion rates of 25-day-old *Mytilus galloprovincialis* larvae on *Scrippsiella trochoidea* as a function of mean prey concentration. Symbols represent treatment means \pm 1 SE. The curves are fitted as in Fig. 10.

Figure 14. Ingestion rates of 25-day-old *Mytilus galloprovincialis* larvae on *Prorocentrum micans* as a function of mean prey concentration. Symbols represent treatment means \pm 1 SE. The curves are fitted as in Fig. 10.

Ingestion and Clearance

Data from this study show that the maximum ingestion rates of 25-day-old *M. galloprovincialis* larvae on each red-tide dinoflagellate species measured in Experiments 8 to 13 are poorly correlated with prey cell volume (Fig. 16). This relationship suggests that prey cell volume does not have an affect on ingestion by the larvae

Figure 15. Ingestion rates of 25-day-old *Mytilus galloprovincialis* larvae on *Lingulodinium polyedrum* as a function of mean prey concentration. Symbols represent treatment means \pm 1 SE. The curves are fitted as in Fig. 10.

TABLE 3.

Grazing data for *Mytilus galloprovincialis* larvae.*

Figures	Species	I_{\max}	K_{IR}	r^2
10	<i>Prorocentrum minimum</i>	26	577	0.72
11	<i>Cochlodinium polykrikoides</i>	69	1510	0.73
12	<i>Alexandrium affine</i>	14	539	0.48
13	<i>Scrippsiella trochoidea</i>	21	269	0.50
14	<i>Prorocentrum micans</i>	56	538	0.61
15	<i>Lingulodinium polyedrum</i>	45	590	0.73

* Parameters are for functional response from Eq. 1 as presented in Figs. 10–15. I_{\max} (maximum ingestion rate, ng C predator⁻¹ day⁻¹), K_{IR} (prey concentration sustaining 0.5 I_{\max} , ng C mL⁻¹).

of red-tide dinoflagellates. Thus, factors other than prey cell volume may be important to the feeding activity of the larvae. Maximum ingestion rates of the larvae on *C. polykrikoides* and *P. micans* were much higher than those for *S. trochoidea* and *A. affine*, even though these prey species are similar in cell volume. However, these results are difficult to interpret. The C:N ratios of *C. polykrikoides* (7.7) and *P. micans* (8.7) are similar to or higher than those for *S. trochoidea* (5.6) and *A. affine* (8.4) (Jeong et al., unpublished data). Thus, nutritional values of prey species may not be responsible for these different maximum ingestion rates. Trochophore larvae of the oyster *Crassostrea gigas* 17 h after fertilization have been shown to be killed when exposed to toxic dinoflagellates (Matsuyama et al. 2001). However, *S. trochoidea* and *A. affine* are nontoxic dinoflagellates (our data). Regarding cell shape, *C. polykrikoides* and *P. micans* cells are compressed, whereas *S. trochoidea* and *A. affine* are spherical. Therefore, the compressed cells may be easier for the larvae to ingest than the spherical cells. However, to determine the exact cause of this pattern, further study is necessary.

Figure 16. Maximum ingestion rates (I_{\max}) of 25-day-old *Mytilus galloprovincialis* larvae on 6 red-tide dinoflagellate species as a function of prey cell volume. Aa: *Alexandrium affine*, Cp: *Cochlodinium polykrikoides*, Lp: *Lingulodinium polyedrum*, Pmc: *Prorocentrum micans*, Pmi: *Prorocentrum minimum*, and St: *Scrippsiella trochoidea*.

The maximum ingestion (I_{\max}) and clearance rates (C_{\max}) of 25-day-old *M. galloprovincialis* larvae on red-tide dinoflagellates obtained in this study (69 ng C predator⁻¹ day⁻¹ and 11.4 μ L predator⁻¹ h⁻¹, respectively) are comparable to or lower than those for *M. edulis* larvae on microflagellates (37–160 ng C predator⁻¹ day⁻¹ and 11–88 μ L predator⁻¹ h⁻¹, respectively) (Bayne 1965, Riisgard et al. 1980, Riisgard et al. 1981, Jespersen & Olsen 1982, Sprung 1984b), when corrected to 15°C using $Q_{10} = 3.4$ (Hansen et al. 1997). The smaller size of *M. galloprovincialis* larvae (193 μ m) with respect to *M. edulis* larvae (250) might be responsible for the former predator's lower C_{\max} .

The I_{\max} and C_{\max} of 25-day-old *M. galloprovincialis* larvae on each red-tide dinoflagellate species are higher than those previously reported for a mixotrophic dinoflagellate, heterotrophic dinoflagellates, or a small ciliate, but much lower than those for large ciliates on the same prey (Table 4). For example, the I_{\max} of *M. galloprovincialis* larvae on *Lingulodinium polyedrum* obtained in this study (45 ng C predator⁻¹ day⁻¹) is higher than those of *Polykrikos kofoidii* (16 ng C predator⁻¹ day⁻¹), *Tiarina fusus* (15), *Protopteridinium cf. divergens* (8), *Fragilidium cf. mexicanum* (5), and *Protopteridinium crassipes* (3), but much lower than that of *Strombidinopsis* sp. (147 ng C predator⁻¹ day⁻¹), when corrected to 15°C using $Q_{10} = 2.8$ (Hansen et al. 1997). The C_{\max} of *M. galloprovincialis* larvae on *L. polyedrum* (11.4 μ L predator⁻¹ h⁻¹) is also higher than those of *P. kofoidii* (3.9), *T. fusus* (3.0), *F. cf. mexicanum* (2.6), *P. cf. divergens* (0.5), and *P. crassipes* (0.3), but much lower than that of *Strombidinopsis* sp. (73). This pattern is maintained in *S. trochoidea*, *C. polykrikoides*, *P. minimum*, and *P. micans* prey. This evidence suggests that engulfing prey in the feeding current produced by the ciliated velum near the mouth (*Mytilus* larvae) is a more effective feeding mechanism than engulfing prey captured by a tow filament (*Polykrikos* spp.) or pallium feeding on prey captured by a tow filament (*Protopteridinium* spp.), but less effective than engulfing prey using rows of cilia in the mouth (*Strombidinopsis* spp. and *Favella* spp.).

Ecological Importance

In the current study, *M. galloprovincialis* larvae fed on red-tide dinoflagellates without mortality after 72 h exposure to considerable high prey concentrations. Thus, the larvae are able to survive during and/or after red tides dominated by these dinoflagellates. Also, dinoflagellates are one of the most abundant phytoplankters in coastal waters, and thus the bivalve larvae may develop healthily by feeding on commonly distributed dinoflagellates. *M. galloprovincialis* larvae, one component of microzooplankters, exhibited higher maximum ingestion and clearance rates than previously reported for other microzooplankters such as the *Fragilidium cf. mexicanum* (mixotrophic dinoflagellate), the *Protopteridinium cf. divergens*, *Polykrikos kofoidii* (heterotrophic dinoflagellates), or *Tiarina fusus* (small ciliate), but lower rates than *Strombidinopsis* spp. and *Favella* spp. (large ciliates) when fed the same prey species. Thus, *Mytilus* larvae may compete with some microzooplankters for dinoflagellate prey.

ABSTRACT The purpose of this study was to compare artificial diets for early juvenile abalone, *Haliotis asinina*, containing different sources of protein. Juvenile *H. asinina* with mean initial shell length of 5.3–5.6 mm were fed artificial diets for 90 days. Diets contained 30% crude protein from different sources: casein, fish meal, soybean meal, and rice bran. The diets were fed to abalone at 5–10% body weight once daily in the afternoon. Abalone fed *Acanthophora* sp. served as a control. The results showed that the abalone fed fresh *Acanthophora* sp. and those receiving the casein-based diet had the highest growth rates in shell length (96.7 ± 8.0 $\mu\text{m}/\text{day}$ and 96.3 ± 6.7 $\mu\text{m}/\text{day}$, respectively). Those fed the casein-based diet showed the highest growth rate in weight (8.6 ± 0.3 mg/day). The best survival rates were found in abalone fed *Acanthophora* sp., the soybean-based diet and the casein-based diet (88.9%, 81.1%, and 78.9%, respectively). The casein diet yielded the maximum rate of growth and survival.

KEY WORDS: comparative growth performance, early juvenile, artificial diets, *Haliotis asinina*

INTRODUCTION

The donkey's ear abalone, *Haliotis asinina* Linnaeus, a very promising commercial abalone in the Southeast Asia region, is a tropical species. It is distributed widely in coastal reef zones of Southeast Asia. In Thailand, research into abalone culturing techniques began in the early 1990s (Singhagruiwan 1989, Singhagruiwan & Doi 1993, Jarayabhand & Paphavasit 1996). Feeding, growth, and survival (Singhagruiwan 1991a, 1991b, Singhagruiwan & Sasaki 1991, Singhagruiwan 1993, Kunavongdate et al. 1995, Upatham et al. 1998, Kruatrachue et al. 2000) have been investigated for adult abalone, but little work has been done on juvenile *H. asinina*.

Culture of *H. asinina* in Thailand is divided into two phases. The first phase is the culture of newly settled spats on corrugated plastic plates coated with diatoms until a shell length of 5–10 mm is attained. The second phase is the culture of juveniles on corrugated cement plates with seaweed until they reach a marketable size (40–50 mm in shell length) (Singhagruiwan & Doi 1993). There are many problems, however, in using natural seaweed, such as seasonality and accessibility (Uki & Watanabe 1992). Artificial diets could solve these problems.

In recent years, there has been a rapid increase in the number of research groups developing artificial diets to supplement or replace seaweeds in abalone culture (Uki & Watanabe 1992, Viana et al. 1993, Fleming et al. 1996, Britz 1996a, 1996b, Capinpin & Corre 1996, Moss 1997, Corazani & Illanes 1998, Lopez et al. 1998, Chen & Lee 1999, Kruatrachue et al. 2000, Serviere-Zaragoza et al. 2001, Boarder & Shpigel 2001, Shipton & Britz 2001, Jackson et al. 2001). Growth of abalone feeding on macroalgae and artificial diets has been studied for *H. discus* Reeve (Ogino & Ohta 1963), *H. discus hamai* Ino (Uki et al. 1985, Nie et al. 1986, Uki et al. 1986a, 1986b, Corazani & Illanes 1998), *H. fulgens* Philippi (Viana et al. 1993, Serviere-Zaragoza et al. 2001), *H. asinina* (Capinpin & Corre, 1996, Upatham et al. 1998, Capinpin et al. 1999, Bautista-Teruel & Millamena 1999, Kruatrachue

et al. 2000, Jackson et al. 2001), *H. iris* Gmelin (Stuart & Brown 1994), *H. tuberculata* Linnaeus (Koike et al. 1979, Mgaya & Mercer 1995, Lopez et al. 1998), *H. laevigata* Donovan (Morrison & Whittington 1991), *H. rufescens* Swainson (Corazani & Illanes 1998), *H. australis* Gmelin (Moss 1997), *H. diversicolor super-texta* Lischke (Chen & Lee 1999), and *H. midae* Linnaeus (Britz 1996a, Knauer et al. 1996, Shipton & Britz 2001). Among these extensive studies, only a few reported on early juvenile growth of abalone.

For commercial abalone culture, it is important to enhance the growth at all stages and therefore information is required on the dietary requirements of each size class. This study was carried out to investigate the growth and survival of early juvenile *H. asinina* fed four artificial diets with different sources of protein: casein, fish meal, soybean meal, and rice bran.

MATERIALS AND METHODS

Abalone

Three-month-old juvenile *H. asinina* (5.5 ± 0.2 mm in length, 45.3 ± 3.7 in weight) were obtained from the Coastal Aquaculture Development Center, Prachuap Khiri Khan Province, Thailand. They were placed in the rearing system for acclimatization and fed *Acanthophora* sp. seaweed for two weeks before collection of initial data.

Preparation of Diets

Diet formulations are presented in Table 1. The diets were prepared following Uki et al. (1986a), using different sources of protein-casein, fishmeal, soybean meal, and rice bran. The vitamin mix in Cetavit 1,000 g was obtained from the Eastern Marine Co., Ltd., Thailand, and mineral mix in Premix 1,000 g was obtained from Chanaphant Industry Co., Ltd., Thailand (Table 2). Equivalent amounts of vitamins and minerals were added to all diets (Table 1).

All dry ingredients were mixed together and then cod liver oil and vegetable oil added. The sodium alginate was heated in 60–80 mL distilled water at 60–80 C, until it melted, then poured into the

Calcium chloride	1	1	1	1

mixed ingredients and kneaded immediately to obtain a homogeneous paste. The paste was flattened with a kitchen roller to a thickness of 0.5 cm. Pieces 1.5 × 1.5 cm in dimension were cut and stored in the freezer until feeding.

Experimental Procedure

There were four dietary treatments: (1) casein-based diet; (2) fish meal-based diet; (3) soybean meal-based diet; and (4) rice bran-based diet. Fresh seaweed (*Acanthophora* sp.) was fed to the control group. Early juvenile abalone (5.3–5.6 mm in shell length, 40–50 mg in weight) were kept in rectangular 5-L plastic aquaria. Thirty abalone were allocated to each trial aquarium (three replicates per diet), and all 12 aquaria were floated in 700-L fiberglass tanks under a close system with aeration and filter system. The tanks were covered to prevent animals from escaping. UV-sterilized and filtered seawater (salinity 32–34 ppt, pH 8.4–8.5) was changed every morning for 90 days. The abalone were fed every afternoon with artificial diets and macroalgae at 5–10% of their body weights. Any uneaten food was collected the following morning to estimate the feed consumed and the food conversion rate (FCR). The light/dark sequence was 12h/12h and the temperature was 29–32 C. Water quality parameters (DO, pH, and temperature) were randomly measured weekly. The total ammonia and the total nitrite were within the standard ranges (0.013–0.191 ppm and 0.016–0.053 ppm, respectively). The dry weight of artificial diets and algae were determined by drying in a hot air oven at 80 C until a constant weight was reached. Growth was measured bi-weekly as gain in weight and shell length and expressed in terms of shell length ($\mu\text{m}/\text{day}$) and body weight (mg/day). Mortality was also recorded every two weeks.

The FCR was calculated on the basis of the total dry weight gain of abalone and the dry weight of feed consumed as follows (Leighton & Booloottian 1963):

$$\text{FCR} = \frac{\text{Dry weight feed consumed (g)}}{\text{Dry weight gain (g)}}$$

At the beginning of the experiment, 15 animals were sampled out to determine their total dry weight. Similarly, at the end of the experiment (90 days), the total dry weight of those animals that

Vitamin B ₁₂	0.05 g
Nicotinamide	20.0 g
Calcium-D-Panthenate	5.0 g
Folic acid	0.4 g
Minerals	
Manganese	5,400 g
Iron	14,200 g
Copper	1,000 g
Zinc	2,900 g
Sodium	3,300 g
Iodine	0.019 mg
Potassium	0.9 g
Cobalt	1.1 g
Medium	971.18 g

survived from each treatment was determined. These animals were weighed and dried at 80 C until a constant weight was reached.

Statistical Analysis

Differences in growth and survival rates, and FCR among the different dietary treatments were determined by one-way ANOVA. The multiple comparisons, Duncan's multiple range test, was further used to determine significant differences between treatments. SPSS for Windows (Version 6.0) was the statistical software used for all statistical analysis. $P < 0.05$ was used as the significance level.

RESULTS

Growth Rate

The results obtained from each artificial diet and the control diet are shown in Table 3 and Figures 1 and 2. Growth rates (shell length and body weight increase/day) of *H. asinina* were significantly different ($P < 0.05$) among feed treatments. In terms of shell length, three statistically different groups could be recognized ($P < 0.05$): (1) control and casein-based diet; (2) fish meal-based and soybean meal-based diets; and (3) rice bran-based diet (Table 3). Four statistically different groups ($P < 0.05$) could be differentiated on weight increase: (1) casein-based diet; (2) control; (3) fish meal-based and soybean meal-based diets; and (4) rice bran-based diet (Table 3).

Shell Length

The maximum cumulative increases in shell length were 161.2% and 164.7% for the control and casein-based diet, respectively (Fig. 1). These equated to growth rates of 96.7 and 96.3 $\mu\text{m}/\text{day}$, respectively (Table 3). Lower cumulative increases of shell length were obtained with abalone fed fish meal-based (111.2%) and soybean meal-based diets (107.8%) (Fig. 1). These

Fish meal-based	71.1 \pm 8.4 ^b	5.5 \pm 0.2	11.7 \pm 0.3 ^b	46.0 \pm 3.5	307.0 \pm 6.1 ^b	111.2 \pm 12.1 ^b	569.6 \pm 46.0 ^b	68.1 \pm 5.0 ^b	2.9 \pm 0.1 ^b
Soybean meal-based	81.1 \pm 3.8 ^{a,b}	5.6 \pm 0.2	11.6 \pm 0.6 ^b	46.0 \pm 3.5	332.3 \pm 38.1 ^b	107.8 \pm 8.6 ^b	621.1 \pm 28.6 ^b	67.0 \pm 5.3 ^b	3.2 \pm 0.4 ^b
Rice bran-based	74.4 \pm 8.4 ^b	5.4 \pm 0.4	9.8 \pm 0.1 ^b	44.0 \pm 5.3	186.7 \pm 10.2 ^d	81.5 \pm 13.6 ^c	327.4 \pm 45.7 ^d	48.5 \pm 4.5 ^c	1.6 \pm 0.1 ^d

Means and standard deviations are presented ($n = 90$). Analysis of variance and Duncan's multiple range test were performed on the means of shell length and body weight increases, the same letter identifies the values that are not significantly different ($P < 0.05$).

gains corresponded to growth rates of 68.1 and 67.0 $\mu\text{m}/\text{day}$, respectively (Table 3). The lowest cumulative increase in shell length was found in abalone fed the rice bran-based diet (81.5%), which equated to a growth rate of 48.5 $\mu\text{m}/\text{day}$ (Fig. 1, Table 3).

Body Weight

The maximum cumulative weight increase (1683.6%) was found in the casein-based diet group that gave a growth rate of 8.6 mg/day (Fig. 2, Table 3). The control also had a high cumulative weight increase (1283.7%) and growth rate of 6.3 mg/day. Abalone fed soybean meal- and fish meal-based diets had lower cumulative increases in weight (621% and 569.6%, respectively) (Fig. 2, Table 3). These equated to growth rates of 3.2 and 2.9 mg/day, respectively (Table 3). The lowest cumulative increase in weight was found in abalone fed the rice bran-based diet (327.4%) that resulted in a growth rate of 1.6 mg/day.

Survival Rate

The survival rates of *H. asinina* fed different artificial diets and on algal control diet were significantly different ($P < 0.05$) (Fig. 3, Table 3). Two different groups could be recognized: (1) control (88.9%), soybean meal-based diet (81.1%), and casein-based diet (78.9%); (2) rice bran-based diet (74.4%) and fish meal-based diet (71.1%) groups.

Figure 1. Percentage shell length increase of *H. asinina* fed artificial diets containing various protein sources over a period of 90 days. ($n = 90$, error bars are standard deviations, three replicates)

Food Conversion Rate

The dry weight FCR was significantly different ($P < 0.05$) among four dietary groups (Table 4): (1) control (0.3); (2) casein-based diet (1.5); (3) soybean meal-based diet (4.0); (4) fish meal-based diet (6.1); and rice bran-based diet (6.4).

DISCUSSION

Early juvenile *H. asinina* provided *Acanthophora* sp. and a casein-based diet (as a main source of protein) produced superior growth rates (for shell length and body weight) and survival rates compared with juveniles fed fish meal-based, soybean meal-based, and rice bran-based diets. The growth and survival rates of the casein-based diet group were not significantly different from those fed macroalgae (control). The dietary value of casein-based diet was comparable to that of the macroalgae. The growth rates in shell length (96.8 $\mu\text{m}/\text{day}$ in the macroalgae group and 96.3 $\mu\text{m}/\text{day}$ in the casein-based diet group) are comparable with that reported by Kunavongdate et al. (1995), who found that juvenile *H. asinina* (31 mm in shell length) fed *Laurencia* sp. yielded a growth rate of 98 $\mu\text{m}/\text{day}$ (Table 5). Upatham et al. (1998) reported a lower growth rate (70 $\mu\text{m}/\text{day}$) in juvenile *H. asinina* (13 mm in shell length) fed *Gracilaria tenuistipitata*. In comparison, Krueatrachue et al. (2000) reported very low growth rates (29–36 $\mu\text{m}/\text{day}$) for juvenile *H. asinina* (13 mm in shell length) fed casein-based diets containing various species of red algae (Table 5). They

Figure 2. Percentage weight increase of *H. asinina* fed artificial diets containing various protein sources over a period of 90 days. ($n = 90$, error bars are standard deviations, three replicates)

Figure 3. Percentage survival of *H. asinina* fed artificial diets containing various protein sources over a period of 90 days. ($n = 90$, error bars are standard deviations, three replicates)

suggested that these formulated diets were unsuitable and significant leaching of some trace nutrients might occur, resulting in poor growth rates (Kruatrachue et al. 2000). Jackson et al. (2001) studied the suitability of Australian formulated diets for aquaculture of *H. asinina* and found that a natural diet of *G. edulis* still produced the highest growth rate ($56 \mu\text{m}/\text{day}$; Table 5), while four formulated diets from two Australian abalone feed companies produced lower growth rates of $19\text{--}54 \mu\text{m}/\text{day}$ (Table 5). However, the growth rates of *H. asinina* of our study were low when compared with the study of Capinpin & Corre (1996) who reported that the growth rates of juvenile *H. asinina* fed *G. heteroclada* and a commercial artificial diet were 193 and $192 \mu\text{m}/\text{day}$, respectively (Table 5). Capinpin et al. (1999) also recorded a shell length growth rate of $164 \mu\text{m}/\text{day}$ for *H. asinina* reared in sea cages and fed *G. bailinae*. Bautista-Teruel & Millamena (1999) achieved growth rates ranging from 222 to $247 \mu\text{m}/\text{day}$ over 90 days when 20 juvenile *H. asinina* (18.3 mm in shell length) were housed in large 60-L containers and fed either of three formulated diets. These are the highest growth rates ever reported for *Haliothis* species (Table 5). In this study, *H. asinina* were reared in small (5-L) enclosures, which may have contributed significantly to the lower growth rates ($49\text{--}96 \mu\text{m}/\text{day}$) compared to other studies. The results are not directly comparable because of differing experimental conditions and the smaller size of juvenile *H. asinina* used in this

study. In general, certain species of red algae seemed to produce higher growth rates in *H. asinina* than artificial diets.

Table 5 also summarizes the reported data on growth rates of abalone fed artificial diets. Most studies evaluated the quality of several protein sources in diets such as casein, fishmeal, and soybean meal. A casein-based diet produced a higher growth rate ($133 \mu\text{m}/\text{day}$) in juvenile *H. discus hannai* (34 mm), compared with those fed either a soybean-based diet ($106 \mu\text{m}/\text{day}$) or a fishmeal-based diet ($74 \mu\text{m}/\text{day}$) for 40 days (Uki et al. 1985). Uki et al. (1986b) also reported a higher growth rate ($82 \mu\text{m}/\text{day}$) in juvenile *H. discus hannai* fed a casein-based diet than in those fed a fishmeal-based diet ($47 \mu\text{m}/\text{day}$), for 50 days. These reported results were in agreement with the results of this study on juvenile *H. asinina* ($5\text{--}6$ mm).

In comparison Britz (1996a, 1996b) reported that a fish meal-based diet produced a higher growth rate ($65.83\text{--}96 \mu\text{m}/\text{day}$) than a casein-based diet ($45 \mu\text{m}/\text{day}$) in juvenile *H. midiae* ($20\text{--}21$ mm) (Table 5). Similarly, Lopez et al. (1998) also reported that a fish meal-based diet resulted in a higher growth rate ($135 \mu\text{m}/\text{day}$) than a casein-based diet ($119 \mu\text{m}/\text{day}$) (Table 5) in *H. tuberculata* (3.2 mm). However, Viana et al. (1993) reported that a casein-based diet and a fish meal-based diet produced similar growth rates ($98 \mu\text{m}/\text{day}$ and $101 \mu\text{m}/\text{day}$, respectively) in *H. fulgens* (13 mm) (Table 5). In *H. asinina* of this study, fish meal-based and soybean meal-based diets produced the second highest growth rates ($68 \mu\text{m}/\text{day}$ and $67 \mu\text{m}/\text{day}$, respectively). The source and the processing of the fishmeal used in these studies may account for these differences. A soybean meal-based diet was also reported to produce high growth rates in *H. discus hannai* ($106 \mu\text{m}/\text{day}$) (Uki et al. 1985) and *H. diversicolor supertexta* ($105\text{--}163 \mu\text{m}/\text{day}$) (Chen & Lee 1999) (Table 5).

The most appropriate diet for *H. asinina* culture depends on the availability and cost of various protein sources and the growth rates produced. Although a casein-based diet produced the highest growth rate in this study, casein is unlikely to be widely used as a primary protein source in practical diets because of its high cost. Fishmeal is more appropriate since it is readily available and less expensive than casein. Even though a fish meal-based diet produced a lower growth rate than casein-based diet in *H. asinina*, in other *Haliothis* species it produced higher growth rates. There is, however, an increasing concern about the future supply and demand for fish meal, and this concern has led to efforts to reduce its use as the major protein source in commercial aquaculture feed formulations (Barlow 1989, Ramsey 1993). Because *Haliothis* are

naturally herbivorous animals with a digestive and enzymatic physiology equipped for processing plant materials. Shipton and Britz (2001) studied the partial and total replacement of fishmeal with selected plant protein sources (soy meal, sunflower meal, torula yeast, corn gluten, and *Spirulina*) in diets for *H. midae*, a

South African species. No significant differences were found in the growth rates between the control diet (100% fishmeal; 83 $\mu\text{m}/\text{day}$) and diets in which 30% of the fishmeal component was replaced by plant proteins (Table 5). Among the plant protein sources, fishmeal with torula yeast produced the highest growth rate (91

$\mu\text{m}/\text{day}$) (Table 5). The lowest growth rate was found in fishmeal and corn gluten (70 $\mu\text{m}/\text{day}$) (Table 5). Substitution of 50% fishmeal with either soy meal or *Spirulina* did not affect growth rates. Replacement of either 75% or 100% fishmeal with plant protein sources (sunflower meal, soy meal, and *Spirulina*) produced growth rates comparable to that of the control. Shipton and Britz (2001) concluded that there was a potential to replace fish meal with plant protein sources in commercial diets for *Haliotis*, especially considering the low raw material costs associated with soybean meal and sunflower meal. This study shows that for *H. asinina*, the soybean meal-based diet, yielded similar growth rates to fishmeal-based diet, and the survival rate was higher. Other factors also affect the growth rate of abalone, including water temperature, (Leighton 1974, Leighton et al. 1981, Uki et al. 1981, Hahn 1989, Lopez et al. 1998), the species of abalone (Uki & Kikuchi 1979), the rearing system (Moss 1997, Chen & Lee 1999) changing the diet of juveniles from diatoms to seaweeds, or artificial diets at the appropriate size. These factors will also affect the early growth of juvenile *H. asinina* and need to be investigated.

In general, abalone fed artificial diets have displayed higher rates of weight gain and length increase, and lower FCR compared with those fed macroalgae (Table 5). FCRs obtained for macroalgae have also differed among species (Table 5). *H. asinina* fed *G. tenuistipitata* and *Acanthophora spicifera* showed lower FCRs

(3.3 and 5.7, respectively) while those fed *G. salicornia*, *G. fisheri*, and *Laurencia* sp. showed higher FCRs (15.5 and 20.4, 7.4 and 29.5, and 18.0, respectively) (Singhagruiwan 1991b, Kunavongdate et al. 1995, Upatham et al. 1998; Table 5). The FCRs of *H. asinina* fed casein-based diets containing various species of macroalgae were higher than those of macroalgae (Upatham et al. 1998, Kruatrachue et al. 2000; Table 5). In contrast, abalone fed artificial diets showed lower FCRs, for example, *H. tuberculata* (0.8–0.9; Lopez et al. 1998), *H. midae* (0.7–1.0; Britz 1996b, Shipton & Britz 2001), *H. diversicolor supertexta* (3.0; Chen & Lee 1999), *H. asinina* (1.4–1.8; Bautista-Teruel & Millamena 1999, Jackson et al. 2001; Table 5). In this study, other than the control (*Acanthophora* sp.), the FCR of the casein-based diet was low (1.5) and similar to those reported by Bautista-Teruel and Millamena (1999) and Jackson et al. (2001). Fleming et al. (1996) reviewed the formulated diets of temperate abalone offered by various feed manufacturers around the world and reported an FCR range of 0.77 to 3.33. The FCR value for the casein-based diet of this study compares favorably.

México

ABSTRACT This report describes a karyotypic analysis in the Pacific red abalone *Haliotis rufescens* using image analysis. This is the first karyotype reported for this species. Chromosome number and karyotype are the basic information of a genome and important for ploidy manipulation, genomic analysis, and our understanding about chromosomal evolution. In this study we found that the diploid number of chromosomes in the red abalone was 36. Using image analysis by rank-order and digital morphologic filters, it was possible to determine total length of chromosomes and relative arm length in digitally enhanced image, elimination of noise and improving the contrast for the measurements. The karyotype consisted of eight pairs of metacentric chromosomes, eight pairs of submetacentric, one pair submetacentric/metacentric, and one pair of subtelocentric chromosomes. The black abalone, *Haliotis cracherodii*, also with 36 chromosomes and with a similar geographic distribution, has eight pairs of metacentric, eight pairs of submetacentric, and two pairs subtelocentric. This study contributes with new information about the karyology in the family Haliotidae found in California Coast waters and gives some support the Tethys' model about biogeographical origin, from the Mediterranean Sea to the East Pacific Ocean.

KEY WORDS: karyotype, *Haliotis rufescens*, chromosome number, image analysis, red abalone

INTRODUCTION

Abalones are economically important marine gastropods that reach moderate-to-high prices in the world market (Oakes & Ponte 1996). To date, only eight species of abalone, *Haliotis corrugata*, *H. cracherodii*, *H. fulgens*, *H. kamtschakana*, *H. kamtschakana*, *H. k. assimilis*, *H. sorenseni*, *H. walallensis*, and *H. rufescens*, have been reported in the further East Pacific (Geiger & Poppe 2000). The Pacific red abalone, *H. rufescens*, is found from southern Oregon to northern California in the United States and to the Baja California Peninsula in Mexico (Lindberg 1992). Aquaculture production of this species began during the last decade in Mexico, where the whole life cycle is managed under controlled conditions.

In addition to the importance on conservation, taxonomic work and karyological analyzes are also useful tools in providing fundamental information for animal breeding programs such as inter-specific hybridization (Miyaki et al. 1997) and chromosome-set manipulation (Arai et al. 1986, Fujino et al. 1987, Kudo et al. 1991, Zhang et al. 1998). A review about the biogeographical origin of the Family Haliotidae reported by Geiger & Groves (1999) using chromosome data in abalone showed that the abalones could be classified in three groups according to their chromosomes number. The first group ($2n = 28$), inhabits the European–Mediterranean area. The second ($2n = 32$) inhabits the Indigo–Pacific region, and the third group ($2n = 36$) represents the abalones of the North Pacific region. Geiger & Groves (1999) suggest that the biogeographical origin of abalone was in the European–Mediterranean area because *H. tuberculata* ($2n = 28$) is a relict species. Most probably this area could have been the starting point of the radiation, extending the distribution of the abalone forward to East from the Indo–Pacific to the North Pacific Ocean. This theory has been called the Tethys' model. In the California Coast, however, karyological data have been performed only for the black abalone *H. cracherodii* (Minkler, 1977). Thus, more studies are necessary to support the Tethys' model and to know the karyology of abalone species from California Coast.

In recent years, great attention has been given to image processing by the use of rank-order statistics. Rank-order and morphologic digital filters can be applied to computer and optical research (Kober et al. 2001a). These digital filters are very efficient in removing additive and impulsive noise, as well as in image enhancing and restoring the microscopical images. The reason for their success in image processing is that they can suppress noise without destroying important image details, such as edges and fines lines. The aim of this work is to describe the karyotype of Pacific red abalone *Haliotis rufescens* by using rank-order and morphologic filters for suppression of noise and enhancing contrast of the chromosomal images.

MATERIALS AND METHODS

Gametes

Pacific red abalone *Haliotis rufescens* were obtained from the broodstock kept in the commercial farm "Abalones Cultivados S.A" at Eréndira, Baja California, México. The abalones were maintained in a 250-L tank with a recirculating sea water system until the spawning induction. Gametes were obtained through induction spawning according to Morse et al. (1977). Eggs were collected in a 25- μ m sieve and resuspended into 2-L container with seawater filtered (0.45 μ m) and irradiated with ultraviolet light. Fertilization was conducted by adding sperm to the eggs suspension at a final density of 50 sperms per egg.

Chromosome Obtaining

Twenty to 24 hours after fertilization, swimming trochophore larvae of Pacific red abalone were placed in a 0.005% colchicine solution for 3–4 h. After the antimitotic treatment, the samples were subjected to 45 min in a hypotonic solution (50% sea water and distilled water). The larvae were fixed in Carnoy solution (3:1, methanol: acetic acid) by rinsing the samples three times in the fixative at intervals of 10 min. Fixed cells were stored at 5°C overnight in a refrigerator. The sample of cellular suspension was made by cell dissociation in 50% acetic acid and strong agitation

*Corresponding author. E-mail: josue@cicese.mx

with a Pasteur pipette. The cellular suspension was then dropped onto a heated microscope slides (45°C) and air dried.

Chromosome Observation via Computer

The chromosomal images were obtained from unstained metaphases. The best 10 images were digitalized with a 24-bit video color frame grabber (model CG-7, Scion Corp.) using a phase-contrast microscopy (Zeiss Axiolab) equipped with a RGB color video camera (model 1040 COHU). To remove impulse noise as well as small undesirable details in chromosomal image, we use rank-order filters with spatially connected neighborhoods (Kober et al. 2001a, 2001b). These filters use spatial and rank information of spatially connected areas of the input image within a moving window to produce the output. The used rank algorithm

consists of two steps. Outliers and small details are first detected using spatial relationships between the color image components. Then, the detected pixels are replaced with the output of the vector median filter over a local spatially connected area excluding the outliers, while desired detail and noise-free pixels are left unaltered. The size of a moving window is 7×7 elements. The spatially connected neighborhood called as a *CEV* neighborhood is defined as a subset of pixels ($v_{n,m}$) of the moving window, which are spatially connected with the central pixel $v_{k,p}$, and whose values deviate from the value of the central pixel at most by predetermined quantities. The rank filter is given by:

$$\hat{v}_{n,m} = \begin{cases} v_{n,m}, & \text{if } SIZE(CEV[v_{n,m}]) \geq Thrd \\ MED(S[v_{n,m}] - CEV[v_{n,m}]), & \text{otherwise} \end{cases}$$

Figure 1. A, Digital image of metaphase plate from larvae of *Haliotis rufescens*. B, Karyotype of Pacific red abalone *Haliotis rufescens*.

where *Thrd* is a threshold value of either outlier or undesired detail detection. "-" denotes the set difference operation; *S* is a small subset of the pixels of the moving window. The pixels associated with outliers after the detection are excluded from the *S* neighborhood. *MED* and *SIZE* denote the median operation and the size of a set, respectively.

Identification of homologue chromosomes was performed by digital correlation. After identification of homologue chromosomes, determinations of chromosome arm lengths (short and large) were measured with an Image Pro-Plus software version 4.0 (Media Cybernetics). The measurements were used for determining relative lengths of chromosomes and centromeric index ($100 \times$ length of short arm/total chromosome length). The relative lengths of the chromosome arm was plotted the karyo-ideogram according to Spotorno (1985). Karyotype was arranged by decreasing size and classified according to Levan et al. (1964).

RESULTS

All chromosomal images in this study were processed using image analysis. The original digital images were obtained with the CCD camera, in this images were preset noise and contrast low, however, after digital image processing it is observed a good performance on image edge, enhanced contrast of the chromosomes and allowing mensurations morphologic more exact. Figure 1A, shows the images enhanced of unstained metaphase plate by the algorithm.

The karyological observations on larvae of Pacific red abalone showed a diploid number equal to 36 chromosomes (Fig. 1A). The distribution of relative chromosome lengths observed was derived to perform the karyotype of Pacific red abalone *Haliotis rufescens* (Fig. 1B). The mean values and standard deviations of the relative lengths and total lengths of 18 chromosomes pairs were estimated from arm length measurements in well-spread unstained metaphase plates from the larvae using chromosomal image analy-

sis, the maximum length of the chromosomes was $5.67 \pm 0.56 \mu\text{m}$ and the minimum was $3.75 \pm 0.071 \mu\text{m}$ (Table 1). The ratio of the chromosomes arms plotted in the karyo-ideogram indicated that this species possessed eight metacentric pairs (chromosome Nos. 1, 3, 6, 7, 14, 15, 17, and 18), eight submetacentric pair (nos. 2, 4, 5, 8, 9, 10, 11 and 13), one pair (no. 12) was classified as submetacentric/metacentric chromosome and one pair of subtelocentric chromosome (no. 16). Chromosome pairs 14 and 17 were difficult to identify using only such morphologic characteristics as the relative length, because of their mutually overlapping standard deviations (Fig. 2).

DISCUSSION

To our knowledge, this is the first report of ploidy level and chromosome number in the Pacific red abalone *Haliotis rufescens*. Karyological studies of abalone species belonging to the North Oriental Pacific are scarce; in fact, only the karyotype of the black abalone *H. cracherodii* is described with $2n = 36$ (Minkler, 1977), since unknown the karyology of Pacific red abalone *H. rufescens* in the California Coast at present. In contrast, karyological studies in abalones species have been reported in North Occidental Pacific (Arai et al. 1982; Nakamura 1986; Okumura et al. 1999). The morphologic comparison between *H. rufescens* and *H. cracherodii* showed that both species comprised 36 chromosomes. However, they are only similar in the metacentric chromosomes number equal to eight pairs. The differences are that red abalone has nine submetacentric pairs (chromosome no. 12, which is submetacentric/metacentric) and one subtelocentric pair, whereas the black abalone has eight submetacentric pairs and two subtelocentric pairs. This conformation of the karyotype in *H. cracherodii* suggest a deletion process of the short arm in one of submetacentric chromosome pairs, originating an extra subtelocentric pair. It is possible that *H. cracherodii* was divergent from the one species with more number of submetacentric chromosomes. This suggests that *H. cracherodii* has a higher genetic difference than *H. rufescens*. According to Owen et al. (1971) and Leighton (2000), relatively few cases of hybridization in mollusks have been reported, however, in *Haliotis*, with the exception of *H. cracherodii*, each southern Californian species of abalones was found to have hybridized with at least other species. The impossibility the *H. cracherodii* for hybridize with other species of abalones proved genetic distantly related.

Phylogenetic relationships studies by Meyer (1967) among California species were analyzed by immunochemical comparing of the hemocyanins and showed that phylogenetically close species were distinguished from those more distantly related. Two relatively closely related groups were found; 1) *H. rufescens*, *H. sorenseni*, and *H. kamtschaticana assimilis*, and 2) *H. corrugata*, *H. fulgens*, and *H. walallensis* appeared moderately distinct from these groups, whereas *H. cracherodii* was decidedly different from the other species. The amino acid sequences of lysin proteins of seven California abalone species were deduced from the cDNA sequences (Lee & Vacquier 1992, 1995). These studies are in general agreement with the immunochemical comparison by Meyer (1967), but *H. cracherodii* was placed closer to *H. corrugata*, leaving *H. fulgens* in a more distant relationship to the other California species.

Morphometric comparison of chromosomes between the other studied abalone species showed variations of diploid number

PLICOPURPURA PANSA (GOULD, 1853) FROM THE PACIFIC COAST OF MEXICO AND CENTRAL AMERICA: A TRADITIONAL SOURCE OF TYRIAN PURPLE

LUDWIG C. A. NAEGEL*

Centro Interdisciplinario de Ciencias Marinas, Instituto Politécnico Nacional (CICIMAR/IPN), La Paz, B.C.S. 23000, México

ABSTRACT Most marine snails of the families Muricidae and Thaididae, which make up the genera *Murex*, *Thais*, and *Plicopurpura*, produce in the hypobranchial gland (mucus gland) a viscous liquid secretion. The secretion contains, besides mucus and biologically active compounds, minute amounts of chromogens, which develop enzymatically and under the influence of light and oxygen into a purple pigment known as “Tyrian purple,” “Royal purple,” or “Shellfish purple.” Throughout history, humans have used the pigment for various purposes. On the Pacific Coast of Mexico and Central America, for at least 500 y, the dyeing properties of the “snail’s ink” have been known and the pigments used for ceremonial and funeral garments. Here, the muricid *Plicopurpura pansa* (Gould, 1853) is the most exploited, and rarely the thaid *Thais kioskiformis*. *T. kioskiformis* has to be killed to obtain a few drops of the secretion from the hypobranchial gland, in contrast to *P. pansa*, which can be “milked” periodically without harming the animal to obtain a few milliliters of mucus containing the “Tyrian purple” precursors. In contrast to the Mediterranean region, where the use of purple from marine snails has long been forgotten and the craft of dyeing today cannot exactly be reconstructed, in remote Pacific regions of Mexico (in the states of Oaxaca and Michoacan) and in the Indian community of the Borucas in Costa Rica, its use continues until the present day on a small-scale and represents the survival of a knowledge of considerable antiquity. However, it is feared that this old tradition will be lost in the near future. The scarcity of the snails, the time, patience, and labor required for collecting them; and the great numbers of them required to dye a small piece of material are the main reasons why cheap, synthetic pigments are today used for dyeing traditional dresses.

KEY WORDS: *Plicopurpura pansa*, purple snail, Tyrian purple

INTRODUCTION

A large number of publications exist about the use of shellfish purple as a dye, mainly describing the source from Mediterranean snail species. Recently described was the source and chemistry of Tyrian purple from the west Pacific marine snail species *Plicopurpura pansa* (Naegel & Cooksey 2002). General references about the use of Shellfish purple are the books by Schweppe (1993) and Cardon (2003).

The majority of purple-producing marine snails belong to the family of Muricidae and most, if not all, produce a colorless secretion in the hypobranchial gland (also called mucus gland), which turns purple on exposure to air and light (Fretter & Graham 1994), giving what is known as “Tyrian purple,” “Royal purple,” or “Shellfish purple.” Mollusk purple as such does not occur in the live animal, but is formed during a sequence of chemical reactions in the presence of oxygen and light from the secretions produced by the animal. As in antiquity in the Old World, the use of muricids for dyeing led also on the Pacific Coast of the Americas to a product of high economic value. However, in contrast to the Mediterranean region, where the use of purple from marine snails has long been forgotten and the craft of dyeing today cannot exactly be reconstructed, in remote Pacific regions of Mexico (in the states of Oaxaca and Michoacan) and in the Indian community of the Borucas in Costa Rica, its use on a small-scale continues until today and represents the survival of a knowledge of considerable age (Turok 1999). As in the Old World, the conservative Indian communities in Mexico are convinced that Tyrian purple possesses properties that cannot be duplicated, apart from the practical advantage that material dyed with purple does not bleach. Cheap and fast synthetic dyes of purple color are today available, but the communities still prefer the expensive snail-purple. The garlic-like smell of material dyed with snail-purple, which aroma fades only after

several washings, is valued as a proof of authenticity (Gerhard 1962). Additionally, in various parts of the Americas, shellfish purple has long been used in the bridal dress of Indian women. Here, we may have an explanation for the great esteem in which shellfish coloring has been held on this continent, and consequently an analogy with the Old World belief that the purple from snails helps a woman to become prolific. There is also the possibility of a similar early idea that dye mollusks give protection from evil spirits or that shellfish colors are in some long-forgotten way connected with power, royalty, and religion (Gerhard 1962, Yoshioka 1974).

The use of muricids for dyeing cotton on the Pacific Coasts of Mexico and of Central America dates at least from Columbian times. Here, mainly *Plicopurpura pansa* (Gould, 1853) is exploited for Tyrian purple production. The carnivorous, gonochoristic marine snail inhabits intertidal rocks exposed to the open sea with high impact waves. The range of *P. pansa* extends to the Pacific from the northwest coast of Mexico (Baja California Sur) (Clench 1947; Keen 1971) to northern Peru (Peña 1970, Paredes et al. 1999). At low tides the mollusk is relatively easily gathered, and it ejects its dye-producing liquid in such a quantity that there is no need to kill the animal to obtain the purple. Furthermore, the dye-producing hypobranchial gland is so active that the snails can be “milked” periodically. The secretion is a milky-white liquid, which turns on exposure to air and light, at first yellow, then greenish, bluish, and finally purple (“Tyrian purple”).

The knowledge about the use of Tyrian purple on the Pacific side of Central America and Mexico before Columbus is very limited. Because of the tropical humid climate, the preservation of textiles is poor, and because the purple from *P. pansa* can be obtained without the need to kill the animal, shellfish middens are not found, as in Mediterranean and South American locations. However, we have written evidence of this ancient industry from several places in Central America, especially from the 17th and 18th centuries.

HISTORICAL WRITTEN REPORTS ABOUT THE USE OF TYRIAN PURPLE

Possibly the first written report about the traditional use of Tyrian purple in Central America comes from the preacher Thomas Gage of England. Gage writes: "About Chira, Golfo de Salinas and Nicoya [Costa Rica] there are some farms of Spaniards, few and very small Indian towns who are all like slaves used by the Alcalde Major, to make him a kind of thread called pita [pita is made of agave fiber], which is a very rich commodity in Spain, especially of that color wherewith it is dyed in these parts of Nicoya, which is a purple color, for which the Indians are here much charged with work about the seashore, and there to find out certain shells, wherewith they make this purple dye. *Purpura* is a kind of shell-fish whose usual length of life is seven years. He hides himself about the rising of the Dog-star and so continues for 300 days. It is gathered in the spring time and by a mutual rubbing of one or the other of them together, they yield a kind of thick slime like soft wax, but its famous dye for garments is in the mouth of the fish and the most refined juice is in a white vein. The rest of his body is void and of no use. Your Segovia cloth dyed therewith for the richness of the color is sold at five or six pounds the yard, and used only by the greatest Dons of Spain [most probably Spaniards living in the Americas, since during this time Tyrian Purple was not used any more in Europe] and in ancient times only worn by the noblest Romans and called by the name of Tyrian purple. There are also shells for other colors, which are not known to be so plentiful in any other place as here." (Gage 1655).

Unfortunately, Thomas Gage did not describe in more detail which other gastropods were exploited for their Tyrian purple. The literature reports that related species of muricids produce various shades of purple, depending on the number and concentration of different chromogens, and the quantity of liquid produced varies greatly from one species to the next. Additionally, at certain seasons, the mucus gland (hypobranchial gland) is more active and its secretion is altered (Born 1936; Clench 1947; Gerhard, 1962).

Probably because of the over-exploitation of *P. pansa*, it became in Nicoya increasingly difficult to collect snails for dyeing, which caused increasing tensions between the gold-hungry Spanish magistrate and the indigenous population. The tensions exploded in 1760 in an uprising by the Indians (Fernández-Guardia 1938).

In 1744, during cartographic research, the Spanish scientists Jorge and Antonio Ulloa observed at Santa Elena close to Guayaquil in Ecuador, and also in Nicoya, the production and use of Tyrian purple from marine snails. Antonio Ulloa (1748) reports: "On the coasts belonging to the province of Guayaquil the finest purple is found. The animals from which it is derived are contained in shells, about the size of walnuts, and live on rocks washed by the sea. They contain a juice or humor, which is taken out, and yields the true purple. . . . Cotton, thread, and other delicate materials are dyed with it. It gives a lively and durable color, which does not lose its luster by frequent washing, but is rather improved thereby, and does not fade through long-continued use and exposure. Near the port of Nicoya the same kind of shellfish is found, and used for dyeing cotton. In both places the dyed yarn is used in making ribbons, lace, and other articles, which are afterwards skilfully sewn and embroidered. All such articles are highly prized on account of their fine and rare color. Various processes are used for extracting the juice or humor. Some kill the animal. They take it out of its shell, and having laid it on the back of the hand, press and

squeeze it with a knife from the head to the tail, concentrating the fluid in the "tail", which was finally cut off, the rest of the animal matter being thrown away. They treat in this way a number of animals until they have a sufficient quantity of juice. They then draw through the thread, which they wish to dye, and no more is required. But the dyed threads do not show at once the purple color they should have. This is not perceived until the whole is thoroughly dry. At first the color is milk-white, then it becomes green and finally purple. Others express the juice without killing the animal. They do not take it entirely out of the shell, but only press it as to cause a certain quantity of humor to be ejected, with which the threads are dyed. The shells are then laid again on the stones from which they were taken. They recover, and after some time give a fresh quantity of juice, but not so much as the first time. If the operation is repeated three or four times, the quantity is very small and the animal dies of exhaustion."

Ulloa continues the description of the dyeing activity in Nicoya: "a group of dyers would spend a month working from one bay to the next, and return during the following moon to "milk" the same animals again. One man could dye as much as a quarter of a pound of yarn in a single tide, or in theory 15 pounds a month. However, little work was done for a week or so near new moon, when it was thought that the dye was too thin or too meagre. It was believed that both the weight and color of shellfish-dyed thread varied according to the time of day, and sellers and buyers agreed upon a specific hour for their transactions."

It is not clear why the dyers found it either convenient or necessary to kill the animals to extract their color. *P. pansa* can be milked periodically without harming the animal. Perhaps of over-exploitation this species became rare, and therefore the dyers had to look for another purple-producing snail. The species of dye mollusk used toward the end of 1800 was probably *Thais kiosquiformis*. The animal was pricked with a needle or cactus thorn and then pressed down into his shell until it reluctantly yielded a few drops. The cotton threads were soaked and put into a bowl with more cotton into which the dye penetrated (Gerhard 1962).

About the process of purple dyeing as practiced in more recent times by the indigenous communities of Nicaragua, Squier (1852) gives us the following account: "Some of the cotton fabrics manufactured by the Indians are very durable and woven in tasteful figures and various colors. The color most valued is the Tyrian purple, obtained from the murex shellfish, which is found on the Pacific coast of Nicaragua. This color is produced of any desirable depth and tone, and is permanent, unaffected alike by exposure to the sun and to the action of alkalis. The process of dyeing the thread illustrates the patient assiduity of the Indians. It is taken to the seaside, when a sufficient number of shells are collected, which being dried from the sea water, the work is commenced. Each shell is taken up singly, and a slight pressure upon the valve which closes its mouth forces out a few drops of the coloring fluid, which is then almost destitute of color. In this each thread is dipped singly, and after absorbing enough of the precious liquid is carefully drawn out between the thumb and finger, and laid aside to dry. Whole days and nights are spent in this tedious process, until the work is completed. At first the thread is of a dull blue color, but upon exposure to the atmosphere acquires the desired tint. The fish is not destroyed by the operation, but is returned to the sea, where it lays in a new stock of coloring matter for a future occasion."

Apart from aspects of conservation, the "milking" of snails has the advantage that a dye can be obtained without interfering foreign substances.

TYRIAN PURPLE AS A COLORANT IN THE CODEx NUTTALL

In antiquity and in medieval times, Tyrian purple was used in special manuscripts ("Purple codices") as a priming color of parchments. In addition, in a pre-Columbian Mixtec (Codex Nuttall) manuscript, Tyrian purple was applied from an as-yet undetermined snail source, however not as priming color, but as paint. The Codex Nuttall was produced between 1468 and 1519 and describes the wars of conquest of powerful armies, which came to the south of Mexico. Distinguished ladies dressed in purple skirts, ponchos, and coats are shown stained with the same color, and chiefs wearing a purple apron and headdresses. Additionally in this manuscript, it is shown that purple was probably used as a body colorant for priests (Turok et al. 1988).

TEXTILES DYED WITH TYRIAN PURPLE

Due to the humid tropical climate in Mexico and Central America, the conditions for textile conservation are poor. However, about fifty years ago, Mayan textile fragments sealed in a jar were found in the state of Chiapas, Mexico. One band of textile was painted purple with a brush on both sides, most probably from *P. pansa*. It is not possible to date these textiles accurately, however, it is believed that the association of textiles together with charred human bones found in sealed jars belongs to a period not long before the Spanish conquest, and possibly immediately after it (Johnson 1954).

ABUNDANCE OF PURPLE SNAILS IN THE PAST

Undisputed evidence on the use of Tyrian purple on the Pacific coast of Central America and Mexico before the arrival of Spaniards is missing. During the Spanish time, three regions of shellfish dyeing could be found: Veraguas (Panama), the peninsula of Nicoya (Costa Rica), and Oaxaca (Mexico). However, it is not clear which exact species of purple snail were exploited in these regions, but most probably *P. pansa* and in cases of over-exploitation also *T. kiosquiformis*.

The peninsula of Nicoya (Costa Rica) was the center for purple production, and materials dyed with purple were exported to Guatemala and Panama. The mayor of Nicoya had exclusive rights for gathering and distributing dyed skeins in Central and South America. The over-exploitation of the purple snails resulted in a reduction of the snail population, similar to what had happened centuries earlier with Tyrian purple in the Mediterranean (Turok and Acevedo 2000). For this reason, the purple industry in Nicoya ceased to exist by the end of the 19th century, and not for a scarcity of dyers or a reduced demand for the product.

About 1880, the English chemist Schunck (1880) received from the west coast of Nicaragua cotton yarn dyed with the ink from *P. pansa*. It is interesting to note his remark that the animals were extracted, as in Ecuador 150 y earlier, from their shells by means of a pin or other pointed instrument, and the blood furnished the purple dye. This way of obtaining the "ink" certainly drastically reduced the snail population.

The use of "shellfish dye" in Mexico was at first reported in 1874 by von Martens (1874). He obtained from Tehuantepec (Oaxaca) a purple-dyed skirt and material with woven-in purple stripes. He mentioned that the high value of purple-dyed "enagua" skirts can be explained by the high number of snails needed, which are not numerous there (von Martens, 1898). In 1909, the ethnologist Zelia Nuttall visited Tehuantepec, and she also reported that the population of the purple snails seemed to be over-exploited and

became scarce, in spite of the careful treatment of the snails during the "ink" collection. Fishermen started to collect purple at Huamelula, and due to the rarity of the snails, to fill their orders they were often forced to proceed as far north as Huatulco—about 100 km along the coastline away from Huamelula—or even to Acapulco (more than 500 km along the coastline from Huamelula). Nuttall continues, "The scarcity of the fish (snails), the great numbers of them required to dye a pound of cotton, and the time, patience, and labor required, amply account for the comparatively high price of three to five gold dollars for one hand-woven skirt (1909).

TYRIAN PURPLE USE IN MODERN TIMES

Nuttall (1909) regrets that fewer and fewer purple skirts are ordered every year, and that the younger generation of women favors the imported and cheaper European stuffs. At Tehuantepec, the modern center for using Tyrian purple, in 1908 not more than about 20 purple garments were woven, and Nuttall predicted that not before long the industry will be extinct. Nearly eighty years later, Thompson (1994) observed that "in the early 20th century in Mexico shellfish purple was in much more widespread use than it is now. The beliefs, languages, and crafts of the Mexican Indians are fast disappearing. The progressive "westernization" of rural Mexico has led people in many villages to abandon their traditional textiles and customs, in favor of factory-made cloth and western-style clothes which are readily available everywhere. Cultural and social decay is continuing to the point that the demand for traditional textiles has almost vanished. Weavers in a few villages formerly noted for their excellent textiles have turned to making more "commercial" articles for sale to people such as tourists, outside their culture—a classic manifestation of the "airport art" phenomenon."

Today only in remote Pacific regions of Mexico (in the states of Oaxaca and Michoacan) and in the conservative Indian communities of the Borucas in Costa Rica has the tradition of dyeing material with the colorant of purple snails survived (Turok 1999). The Borucas are still exploiting *P. pansa* and *T. kiosquiformis* in the traditional way and are using the dye to make designs on woven fabrics (Gerhard 1962).

Today it is relatively easy to produce synthetically 6,6'-dibromoindigo; however, the interest in it is so small that it is not produced commercially (Imming et al. 2001). It can be considered that the market for a special color can change decisively, not due to technical or scientific influences, but due to historical and cultural perceptions. Tyrian purple has experienced changes during the centuries, not only in the technical, but also in cultural views. Originally, it was the sign of wealth and dignity, the symbol of the ruling class, and later as a high position in the church; today these perceptions have changed completely.

In recent years, however, with the gaining of importance of natural colors, the commercial exploitation of the purple snail for dyeing kimonos with natural "Tyrian purple" had reached in Mexico such levels as to threaten the survival of the species. In 1988, *P. pansa* had to be declared a species under special protection by the Mexican government (Anonymous 1988, Anonymous 1994).

P. pansa grows astonishingly slowly (Ramírez-Rodríguez & Naegel 2003). An animal with a total shell length of about 3 cm might be three years old, if not older. From snails of less than 2-cm shell length can be obtained 0.5 mL of secretion and from large

animals of 5–6 cm up to 4 mL (Rios-Jara et al. 1994). It has to be kept in mind, however, that of this volume only a minute proportion consists of the dye precursors. For this reason, it does not astonish that the enormous number of at least 1000 animals has to be “milked” to dye sufficient cotton threads for just three traditional skirts. In view of the slow growth of *P. pansa*, the small amount of colorant excreted, and the large number of snails needed for dyeing just one skirt, it was the right decision of the Mexican government to permit only Indian communities the traditional exploitation of *P. pansa* for its pigments and to declare it a species under special protection. One recent interesting development in Mexico has to be mentioned, which protect the purple snail on one side, and on the other side promote the traditional use of Tyrian purple and offer to the traditional dyers and weavers an income. Multidisciplinary groups, including indigenous Mixtec, Nahoan, and Boruca communities, social and scientific researchers, groups

of dyers and weavers, local, state, and federal authorities, ecologists, fishermen, and the tourism industry have all joined hands formulating an agreement that describes standards for the sustainable use of *P. pansa* and to create a natural protected area with limited access rights to the resource and promoting the snail culture and species conservation for the long-term (Turok and Acevedo 2000).

ACKNOWLEDGMENTS

I would like to thank Chris Cooksey (London) and Ran Boytner (Los Angeles) for their help in digging out old literature and for making suggestions to improve earlier versions of this manuscript. The anonymous reviewers helped with their suggestions to improve the article. STUDY ON HERITABILITY OF GROWTH IN THE JUVENILE SEA URCHIN, *STRONGYLOCENTROTUS NUDUS*

LIU XIAOLIN,^{1,3} CHANG YAQING,² XIANG JIANHAI,^{1,*} DING JUN,² AND CAO XUEBIN²

¹Experimental Marine Biology Laboratory, Institute of Oceanology, CAS, Qingdao 266071, China; ²Key Lab of Mariculture and Biotechnology of the Ministry of Agriculture, Dalian Fisheries University, Dalian 116023, China; ³College of Animal Science and Technology, Northwest Sci-Tech University of Agriculture and Forestry, Yangling, Shaanxi 712100, China

ABSTRACT The heritability of growth of juvenile *Strongylocentrotus nudus* was analyzed using quantitative genetic methods. Twenty-one half-sib groups and 60–63 full-sib groups of juveniles were obtained by artificial fertilization of 3–5 females by single males based on a nested design. The body weight (g) and test diameter (cm) of the young were measured 3 and 5 mo after metamorphosis. Maternal component estimates are significantly greater than paternal component estimates for both weight and diameter at both ages. Greater maternal components suggest large nonadditive genetic effects that could not be differentiated with the available data. Estimates of heritability in the narrow sense calculated from the additive genetic component using a paternal half-sib correlation analysis ranged from 0.2167 to 0.4565 for weight and 0.2059 to 0.4998 for diameter. The results indicate significant maternal effects. The strength of the nested design and the paternal half-sib correlation analysis used in this study make the estimate the most precise and unbiased reported to date.

KEY WORDS: growth, heritability, sea urchin, *Strongylocentrotus nudus*

INTRODUCTION

Sea urchins are one of the most important aquaculture species in the world. The gonads have long been used as a luxury food and as a food source by common people in many countries (Hagen 1996, Hobson et al. 1990, Shimabukuro 1991). Because of over-fishing, interest in aquaculture of sea urchins has greatly increased (Hagen 1998, Lawrence 2001). One of the most important species for aquaculture is *Strongylocentrotus nudus* (Agatsuma 1998, Hagen 1996). Current culture of *S. nudus* has used seeds obtained from wild individuals (Gao and Chang 1999, Liao and Qiu 1999). Analysis of populations of *S. nudus* in Japanese waters show considerable range in size of small individuals, presumably of single cohorts (Agatsuma 1997). This could result from interaction of genetic characteristics and the environment. Vadas et al. (2002) found evidence for intrinsic variability in field populations of *Strongylocentrotus droebachiensis*. It is important to document the degree of heritability of growth in sea urchins because of its implications for both fisheries and aquaculture.

Demonstration of heritability is best done with comparisons of half-sib groups because they are less likely to be affected by environmental influence (Gjedrem 1992). Sib analysis techniques have been used for a variety of important aquaculture species (Benzie et al. 1997, Crenshaw et al. 1991, Hadley et al. 1991, Newkirk et al. 1977, Mallet et al. 1986, Rawson and Hilbish 1990). The purpose of the current study was to estimate heritability of growth in terms of body weight and diameter of juvenile *S. nudus*.

MATERIALS AND METHODS

Experimental Design

This study used a classic nested mating design developed by Comstock and Robinson (1952) to partition the phenotypic variation in juvenile growth into its genetic and nongenetic causes. In this experiment, each of 21 male *S. nudus* was mated to 3–5 females, therefore generating 63 full-sib families and 21 half-sib

families. The effects of males and females nested within males on growth were separated using nested analysis of variance (ANOVA). Juveniles were weighed and their diameters measured at 3 and 5 mo of age.

Genetic Analysis

The covariance among full- and half-sibs provides the basis for the separation of phenotypic variance into genetic and environmental components of variance. The covariance among full- and half-sibs are calculated from the observed components of variance obtained from a three-level nested, unbalanced ANOVA (Table 1) and the General Linear Models procedure of the Statistical Analysis System (SAS) (Freund et al. 1986).

The experiment was a three-level classic nested, unbalanced design. Therefore, the number of offspring in dams and in sires within sires should revise ("revise" means adjust). The Effective Means were computed using the equations:

Effective mean number of offspring in dams within sires:

$$K_1 = [N - \sum(n_{ij}^2/dn_i)]/(D - S)$$

Effective mean number of offspring in dams:

$$K_2 = [\sum(n_{ij}^2/dn_i) - \sum(n_{ij}^2/N)]/(S - 1)$$

Effective mean number of offspring in sires:

$$K_3 = (N - \sum dn_i^2/N)/(S - 1)$$

in which S = number of sires, D = number of dams, n_{ij} = number of offspring of the i-th sire and j-th dam, dn_i = number of offspring of i-th sire, and N = sum of number of offspring of all sires or all dams.

The phenotypic variance (V_p) was separated into the additive genetic variance (V_A), nonadditive genetic variance (V_N), and environmental variance (V_E), and the environmental variance (V_E) was separated into the common environmental variance (V_{EC}) and the specific environmental variance (V_{ES}) using the standard separation of variance components (Falconer 1989). The causal components of variance were estimated from the full- and half-sib covariance using the relationships in Table 2.

Heritabilities were computed using the relationships: $h^2 = V_A / [V_A + V_{NA} + V_E]$

TABLE 1.
Analysis of variance for components of phenotypic variation.

Source of Variance	Degrees of Freedom (df)	Sum of Squares (SS)	Mean Square (MS)	Expected Mean Square E(MS)
Dams	F × M - 1	SS _M		
Sires	F - 1	SS _F	MS _F	$\sigma^2 + k_2 \sigma^2_{M} + k_3 \sigma^2_{F}$
Dams/sires	F × (M - 1)	SS _{M(F)}	MS _{M(F)}	$\sigma^2 + k_1 \sigma^2_{M}$
Offspring (error)	F × M × (n - 1)	SS	MS	σ^2
Total	N - 1	SS _T		

Thus, heritabilities in the narrow sense of paternal half-sib and maternal half-sib and full-sib were computed using the respective relationships:

$$h^2_{HS(S)} = 4 \times \sigma^2_S / (\sigma^2_S + \sigma^2_D + \sigma^2)$$

$$h^2_{HS(D)} = 4 \times \sigma^2_D / (\sigma^2_S + \sigma^2_D + \sigma^2)$$

$$h^2_{FS(D/S)} = 2 \times (\sigma^2_S + \sigma^2_D) / (\sigma^2_S + \sigma^2_D + \sigma^2)$$

Test of significant of heritability: $t = h^2 / \sigma_{h^2}$

Paternal half-sib:

$$V_{(h^2)} = \left(\frac{4}{\sigma^2_P} \right)^2 \left[V \left(\frac{MS_S}{k_3} \right) + V \left(\frac{MS_D}{K_3} \right) \right]$$

$$\sigma_{h^2} = \frac{4}{\sigma^2_P} \sqrt{\frac{2}{k_3} \left(\frac{MS_S^2}{S-1} + \frac{MS_D^2}{N-D} \right)}$$

Maternal half-sib:

$$V_{(h^2)} = \left(\frac{4}{\sigma^2_P} \right)^2 \left[V \left(\frac{MS_D}{k_1} \right) + V \left(\frac{MS_F}{k_1} \right) \right]$$

$$\sigma_{h^2} = \frac{4}{\sigma^2_P} \sqrt{\frac{2}{k_1} \left(\frac{MS_D^2}{D-S} + \frac{MS_F^2}{N-D} \right)}$$

Full-sib:

$$\sigma_{h^2} = 2 \sqrt{\frac{2(1 - r_{FS})^2 [1 + (k_1 - 1)r_{FS}]^2}{k_1(k_1 - 1)(D - 1)}}$$

Experimental Animal

Collection and Maintenance

Parental *S. nudus* were taken from a cultured population in Dalian Bay on the northern coast of the Yellow Sea on 10 September 2001. These individuals were held at 18–22°C under 500 lx

illumination and fed *Laminaria japonica ad libitum* for 32 days before spawning on 12 October 2001.

Fertilization

Individuals were removed from the aquaria and allowed to drain for 30 min before 1 mL 0.5 M KCl was injected into the coelomic cavity via the peristomial membrane. They were placed on the tops of flasks filled with seawater, and the eggs and sperm were collected from each individual for 30–60 min.

The eggs of each female were fertilized with sperm from a single male. Approximately 150,000 eggs from each female were placed in 100-L containers. Sperm were diluted 1000-fold (Uehara et al. 1990), and a small amount of the diluted sperm was added to the eggs. Fertilization success was examined microscopically. The fertilized eggs were washed 2–3 times to remove excess sperm. The embryos were layered on the bottom of flasks and transferred into a 50-L container to develop at 17–21°C at a density of 4–5 individuals/mL. Normal plutei developed in 30–35 h (Rahman et al. 2000, Rahman et al. 2001).

Rearing

The larvae were transferred to 100-L containers of filtered seawater at 16°C. Densities of larvae from the 2-arm to the 8-arm stage were maintained at 1–2 individuals/mL. The water was changed twice daily. The larvae were fed *Chaetoceros gracilis*. Light was maintained at <300 lx. A small amount of air was bubbled into the water. After three months the juveniles from each fertilization group were placed separately into plastic cages suspended in a large pool. The juveniles were fed fresh *Laminaria japonica*. The cages were changed every 2 mo. The juveniles were weighed and their diameter measured at ages 3 and 5 mo.

RESULTS

Growth: Increase in Body Weight and Test Diameter

Mean and standard deviation of the increase in body weight and test diameter of offspring at 3 and 5 mo of age are given in Table 3.

TABLE 2.
Relationships between the covariance of full- and half-sibs and causal components of phenotypic variance.

5 mo	1.366	0.377	8.492	2.841

Analysis of Variance of Body Weight and Test Diameter of Offspring

Analysis of variance demonstrated great differences in body weight and diameter of juveniles from different females mated with the same male and between males at both 3 and 5 mo of age (Table 4).

Effective mean number of offspring for sires and dams after 3 mo was computed as follows: effective mean number of offspring in dams within sire is $K_1 = 34.689$, in dams is $K_2 = 38.821$, and in sires is $K_3 = 107.719$. Effective mean number of offspring for sires and dams after 5 mo was computed as follows: $K_1 = 33.505$, $K_2 = 36.831$, and $K_3 = 109.268$.

The causal components of variance were estimated from the full- and half-sib covariance using the relationships in Table 5.

Estimations of Heritability of Body Weight and Test Diameter of Offspring

Heritabilities in the narrow sense of paternal half-sib and maternal half-sib and full-sib of body weight and diameter of 3-month-old *S. nudus* were calculated on the result of component of variance and test ($t = h^2/\sigma_e^2$) of significance of heritability, respectively, as shown in Table 6.

All of the heritability in the narrow sense of sire half-sib and the heritability in the broad sense of dam full-sib of body weight and test diameter of *S. intermedius* were significantly different from zero (t -test, $P < 0.01$).

Estimated heritability was somewhat different among the sire heritability, dam heritability, and the pooled (combined) heritabil-

ity for all three traits. The estimates of dam heritability were higher than those of sire heritability, and the pooled (combined) heritability was moderate.

DISCUSSION

Predicted heritabilities of larval growth have been reported for full-sib correlation analysis for *Crassostrea virginica* (Hadley et al. 1975, Lannan 1972, Newkirk et al. 1977) and *Penaeus vannamei* (Carr et al. 1997) and half-sib correlation analysis for *Mercentaria mercenaria* (Rawson and Hilbish 1990), *Macrobrachium rosenbergii* (Malecha et al. 1984), *Penaeus vannamei* (Benzie et al. 1996, Carr et al. 1997), and *Penaeus stylirostris* (Benzie et al. 1996). Predicted heritabilities of shell traits in wild *Littorina saxatilis* populations have been reported for full-sib correlation analysis and offspring-mother regression (Carballo et al. 2001). Estimates of heritabilities in the narrow sense generally ranged from 0.2 to 0.7. Realized heritability for increase in rate of growth in northern quahog and *Argopecten irradians concentricus* (Crenshaw et al. 1991, Crenshaw et al. 1996) and realized heritability estimates for growth in the Chilean oyster *Ostrea chilensis* (Toro et al. 1995). In our study, the estimates of heritabilities in the narrow sense for body weight at 3–5 mo of age ranged from 0.217 to 0.457, consistent with those reported for other species. However, estimates based on full-sib families bias heritabilities upwards when dominance and maternal effects are present (Lester 1988). Because of the nested design and a paternal half-sib correlation analysis used, the estimate reported here is more precise and unbiased. This is the first report of heritability in the narrow sense reported for sea urchins.

An animal model includes a random effect for the additive genetic effect of each individual; incorporates a complete set of additive genetic relationships among all individuals; and allows an unbiased estimation of variance components, even for the data involving selection and nonrandom mating (Gall and Bakar 2002, Sorensen and Kennedy 1986, Su et al. 1997). In the current investigation, full-sib family was taken as a random effect in a simple random model to account for the covariance among full-sibs caused by common environmental, dam, and nonadditive genetic

effects, and half-sib family was used to account for covariance among half-sibs caused by common environmental, dam, sire, and nonadditive genetic effects. The results from the analyses based on this model were expected to be unbiased estimates of genetic parameters for the base population.

The much larger heritabilities computed from the female additive genetic component indicate the female genetic component still contains common environmental effects, maternal effects, or non-additive genetic variance in the body weight or diameter. Dam effects are omnipresent in the study. The fact that the juvenile phase may indicate that the quality of yolk reserves plays a role in

early development. Dam effects may persist after the onset of exogenous feeding. Crandell and Gall (1993) reported that dam effects persist up to 2 y in rainbow trout and up to 18 mo in Arctic char (Nilsson, 1994).

The estimated heritability indicates significant additive genetic variation for body weight and test size over all the sampling periods. Sire heritability for the different variables were lower than dam heritability in many cases. However, all heritabilities in the narrow sense of body weight and test diameter of *S. intermedius* were significantly different from zero ($P < 0.01$). The heritabilities in the narrow sense estimate obtained from this experiment indicate there is sufficient variation in the base population of sea urchins to respond to natural or artificial selection on juvenile growth weight. This justifies selection of juveniles based on growth characteristics for cultured brood stock.

TABLE 6.

Heritabilities in narrow sense (h^2) and standard error (σ_{h^2}).

	3 Mo of Age		5 Mo of Age	
	Body Weight	Diameter	Body Weight	Diameter

UTILIZATION OF LOG-PILING STRUCTURES AS ARTIFICIAL HABITATS FOR RED KING CRAB *PARALITHODES CAMTSCHATICUS*

BRADLEY G. STEVENS,* J. ERIC MUNK, AND PETER A. CUMMISKEY

National Marine Fisheries Service, Alaska Fisheries Science Center, Kodiak Fishery Research Center, 301 Research Ct., Kodiak, Arkansas

ABSTRACT Artificial habitats or reefs have been used to mitigate for alteration of marine habitats and increase populations of desirable marine species. In Kodiak, Alaska, breakwater construction covered 3.5 ha of sedimentary habitat potentially usable by commercially valuable red king crab *Paralithodes camtschaticus*. Juvenile king crab are common occupants of wooden dock pilings, suggesting that pilings could be used to mitigate for loss of natural habitat. To test this hypothesis, six log-piling structures were constructed from untreated spruce and placed in pairs at three different locations in ocean bays near Kodiak. Divers conducted a yearlong study of king crab recruitment by making quarterly counts of crab on the structures and adjacent seafloor areas. Abundance of juvenile (9–21 month-old) king crab increased steadily from June 1997 through March 1998 as crab recruited to the structures, then declined in June 1998. Crab abundance was significantly higher on piling structures than on the adjacent substratum. Site, season, and their interaction had significant effects on abundance. Why juvenile king crab are attracted to pilings is unknown. Pilings are not structurally complex habitats, but provide hard surfaces for fouling organisms such as hydroids, which are preferred habitat for juvenile crab. Additionally, pilings do not persist in the environment, and may not be the best structure for habitat enhancement. For these reasons, and because there is no evidence that red king crab are habitat-limited in our study area, we do not recommend the use of pilings as artificial habitats for red king crab.

KEY WORDS: king crab, habitat, ecology, settlement, artificial reefs, *Paralithodes*

INTRODUCTION

The use of artificial reefs for enhancement of marine populations has received considerable attention in recent years (for examples see Jensen 2002). Such structures may be assembled from a variety of components including natural (logs and rocks), semi-natural (concrete blocks, modules, or concreted boulders), and non-natural (tires, coal ash, wrecked ships, junked cars, and derelict oil platforms). Reefs have been constructed for a variety of recreational and commercial uses, including fisheries enhancement, scuba diving, aquaculture, habitat restoration, environmental mitigation, resource conservation, and research (Seaman 2002). Over time, research on artificial reefs has developed from purely observational studies of colonization, to studies of their ecological function, design and placement, and performance evaluation (Seaman 2002). A major issue in research on enhancement structures has been the "attraction-production" debate: do artificial structures support increased production of target species, or simply attract them from somewhere else? Conflicting viewpoints often depend on assumptions about whether reef-associated species are limited by habitat availability (Grossman et al. 1997) or recruitment variability, making artificial reefs little more than elegant fishing tools (Bohnsack et al. 1997). Lindberg (1997) argued that the answer depends on the specific structure, its location and objectives, and the species considered. Generally, production can be improved by use of highly complex structures that provide high levels of structural heterogeneity at appropriate scales. Such structures probably function to reduce mortality during critical life stages by reducing predation, and providing improved foraging opportunities (Bohnsack et al. 1997).

Most studies of artificial reefs to date have focused on highly mobile fauna such as reef-associated or pelagic fishes. Those dealing with benthic resources have addressed fouling organisms (Foster et al. 1994), or epibenthic prey species (Jara & Cespedes 1994)

of very low motility. Few have studied the use or impacts of artificial structures on commercially significant decapod crustaceans, which are highly motile within limited ranges. Notable exceptions include studies of Florida spiny lobsters *Panulirus argus* (Herrnkind & Butler 1986, Butler & Herrnkind 1997, Herrnkind et al. 1997a, Herrnkind et al. 1997b). These researchers have demonstrated that habitat availability limits the abundance of juvenile lobsters, and enhancement with appropriate artificial substrates can greatly increase abundance, whereas artificially increasing the abundance of juveniles by seeding is not effective. Such increases occur primarily through settlement rather than by immigration (Herrnkind et al. 1997a).

In 1997, a new breakwater was constructed by the United States Army Corps of Engineers (USACE) at the south end of St. Herman Harbor, Near Island, Kodiak, Alaska. During construction of the breakwater >3.5 ha of sedimentary habitat were covered with rock, at depths from 5–20 m, raising concerns that such habitat alterations might displace economically important marine species, particularly red king crab *Paralithodes camtschaticus* (Tilesius, 1815) (hereafter referred to as RKC).

At Kodiak, RKC up to 1.5 y of age are commonly found on wooden pilings covered with a variety of fauna as biologic structure, suggesting that pilings associated with piers are good habitat for juvenile crab. Based on the results of previous studies, (Dew et al. 1992) the National Marine Fisheries Service (NMFS) convinced the United States Coast Guard not to remove a condemned pier (Marginal Pier) in Womens Bay, Kodiak Island, Alaska, which contains hundreds of pilings and is a common site for juvenile king crab of 10–25 mm carapace length (CL). The USACE also installed 50 pilings at a site in Womens Bay as additional crab habitat; although these pilings were not routinely surveyed, we occasionally observed RKC there, though most of the pilings were destroyed by ice within a few years.

This study was undertaken to determine whether juvenile RKC would recruit to submerged log piling structures, and if they could be used to mitigate for habitat alterations caused by construction of breakwater and marina facilities.

MATERIALS AND METHODS

Six log piling structures (Fig. 1) were built and deployed in pairs. Each structure consisted of four 30-cm diameter corner posts (3 m spruce logs with intact bark) sunk into $0.6 \times 0.6 \times 0.5$ m concrete blocks. Adjacent and opposing pairs of corner posts were connected by horizontal 5×20 cm ($\leq 2 \times \leq 8$) beams of rough milled spruce, and similar beams connected the base of each post to the upper cross beam (see Fig. 1). Each structure had a surface area of approximately 35 m^2 . Two structures, labeled North (N) and South (S), were placed in approximately 10 m of water at each of 3 sites (Fig. 2): inside the breakwater (IB), outside the breakwater (OB), and in Womens Bay (WB), approximately 8 km away. The paired structures at the IB and OB sites were placed 27.4 m and 57.3 m apart, respectively. Although both sites were within 100 m of the rock breakwater, we did not survey it because the profusion of kelp prevented adequate sampling of the rock surface and crevices. In Womens Bay, the North and South structures were separated by about 600 m but were placed 34.1 m and 39.3 m, respectively, from Marginal Pier. Marginal Pier is a +60-year-old dock consisting of hundreds of creosote-treated wooden pilings, many of which have decayed, and most are covered with fauna including sponges, anemones, hydroids, bryozoans, barnacles, and sea stars. A fourth pair of survey sites included four Marginal Pier pilings nearest to each of the WBN and WBS habitats; these were labeled MPN and MPS, respectively. All log-piling structures were placed on the seafloor between May 19 and 22, 1997 prior to settlement of the 1997 year-class of RKC.

To compare counts of organisms on the structures to the surrounding environment, benthic transect lines were staked out on opposite sides of each structure. These also served as guidelines between the structures at the IB and OB sites. Because the IB structures were closest together, the standard transect length was defined as half the distance between them, or 13.7 m. Transects of similar length were established on the opposite sides of each structure as well. Surveys were conducted by scuba every 3 mo from June 1997 to June 1998 for a total of five quarterly samples.

Figure 1. Design of the log piling structures used in the study. All were constructed of untreated, rough-milled spruce, held together by large bolts, and anchored by concrete bases.

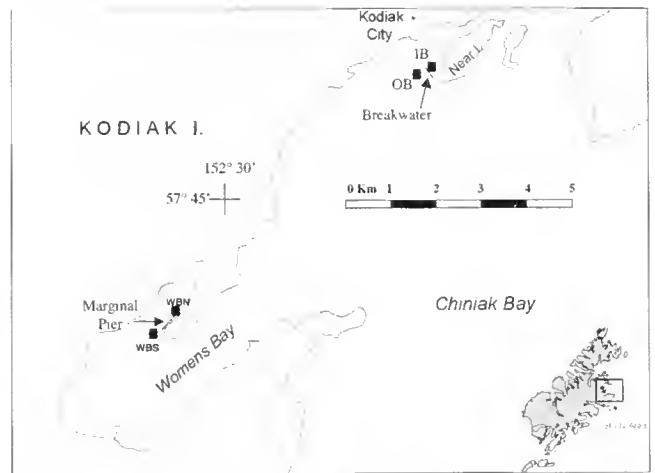

Figure 2. Location of Kodiak, Alaska, and sites of piling structure placement. IB, inside Breakwater; OB, outside Breakwater; WBN, Womens Bay North; WBS, Womens Bay South.

During each survey, divers descended a marker line to the bottom and counted all RKC on the outside and inside of the structure. Divers then counted RKC within a 1 m swath along both sides of the benthic transect lines. Each transect count was treated as an individual replicate. The total bottom area surveyed around each structure was 54.8 m^2 (2 transects \times 2 m \times 13.7 m). Divers then swam to the second structure at the site and repeated the structure and transect counts. Both structures at a site were surveyed on a single day, and each site on separate days within a week. At Marginal Pier, divers also counted RKC on the bottom 3 m of the four pilings nearest to each structure. The total data matrix consisted of 100 samples (5 seasons, 3 sites, 2 structures, 3 locations (structure, transect 1, transect 2), plus two MP samples in each season). To prevent disturbance or displacement, sizes of RKC observed by one diver (JEM) were estimated in 5-mm increments of carapace length (CL). During each dive, a series of replicate photographs were taken at specific locations, including piling tops, sides, crossbeams, concrete bases, and on the transects. Qualitative observations of substrate characteristics and sessile epibenthic species on the piling structures and transects were made from these photographs.

Preliminary data analysis showed that variances among samples were not homogeneous, indicating severe departures from normality that were not remedied by square root or angular trans-

Figure 3. Counts of red king crab at each site, by sampling quarter. IB, inside Breakwater; OB, outside Breakwater; WB, Womens Bay.

formation. For this reason, and because the data are counts of (relatively) rare events, we chose to use a generalized linear model (GLM) type of ANOVA, based on a Poisson distribution rather than the normal distribution. The GLM allowed us to model RKC counts as a function of several factors. Only the data from the structures was analyzed in this manner; transect counts were excluded because of their low numbers, and counts from Marginal Pier were excluded because they were a different type of piling (older, creosote treated). The latter were only compared with the adjacent structures in Womens Bay. Factors included in the analysis were quarter, site, structure (north or south within pairs), and 2-way interactions between those 3 variables. Following this, a nonparametric Mann-Whitney *U*-test was used to make comparisons between pairs of sample sites. Sites compared were Marginal Pier versus site WB, site IB versus site OB, site IB versus WB, and OB versus WB. Statistical analysis was conducted using S-Plus version 4.5 or SPSS version 10.

RESULTS

A total of 136 RKC were observed and counted (Table 1). The largest number of RKC (90 crab, or 73% of the total excluding Marginal Pier) were observed at the OB site, followed by WB (25 or 20%), Marginal Pier (12), and IB (9). Excluding Marginal Pier samples, virtually all RKC (99%) were observed on the structures, and only two RKC were observed on the transects: one on kelp and one on a boulder. At each site, over twice as many RKC occurred on the southern structure (85) as on the northern (37). Only one RKC was observed (on the OB benthic transect) during the first 2 quarters (June and September 1997). By December 1997, young-of-the-year RKC <15 mm CL (9 mo post-hatch) were present on the structures, having probably settled there as post larvae (Table 2). Numbers increased through March 1998, but most were still <15 mm CL. A few crab >25 mm CL, representing the previous

TABLE 1.

Numbers of red king crab counted on log-piling structures, transects and Marginal Pier pilings, in four seasons, at three sites: IB (inside breakwater), OB (outside breakwater), and WB (Womens Bay).

TABLE 2.

Numbers of red king crabs in 5-mm categories of estimated carapace length (CL), observed on piling structures. Only one diver estimated sizes, so this table does not include all crabs observed.

CL Range (mm)	June 1997	Sept 1997	Dec 1997	March 1998	June 1998
10-14	1		3	20	1
15-19			1	4	1
20-24			1		28
25-29				1	
30-34					
35-39				1	1
40-44					1

yearclass (age +1, 21 mo post-hatch) were present on the structures, and probably arrived by immigration. Numbers of RKC observed on structures declined in June 1998; by this time, most crab were in the 20-24 mm CL range.

The Poisson-based GLM showed that the effects of quarter, site, and structure were all significant (Table 3). The interaction of quarter \times site was significant because the highest counts occurred in March 1998 at the OB and WB sites, but counts were highest in June 1998 at the IB site. The interactions of structure \times quarter and structure \times site were not significant. There were not enough degrees of freedom remaining to include a 3-way interaction, and it probably would not have been significant because no 2-way interactions involving structure were significant. The Mann-Whitney *U*-test showed no significant difference in counts of RKC between the WB and MP sites ($U = 45.0$, $P = 0.678$), WB and IB ($U = 39.5$, $P = 0.369$), or WB and OB ($U = 36.0$, $P = 0.267$). Differences between IB and OB were much greater, but still marginally non-significant ($U = 27.0$, $P = 0.057$).

Sediments inside the breakwater were silty and supported a dense community of tube-building polychaetes (possibly *Spiochaetopterus costarum*), whereas sediments outside the breakwater were sandier with scattered rocks and were devoid of epibenthos, except for occasional sea stars. Sediments near the WB structures were also silty, but scattered with mussel shells from Marginal Pier, and occasional anthropogenic debris from 50 y of military use. Calcareous tube-building polychaetes (probably *Serpula vermicularis*) and plumose anemones (*Metridium senile*) were abundant on Marginal Pier and adjacent debris.

TABLE 3.

GLM analysis for effects of factors on counts of red king crabs on piling structures (N or S) in five quarters, at three sites. Data from transect counts and marginal pier are excluded. All data were transformed to $\log(x + 1)$ prior to analysis.

By July 1997, approximately 3 wk after placement of the structures, barnacles of 1–2 mm diameter had colonized most of the structures. Mottled sea stars (*Evasterias troschellii*), sunflower stars (*Pycnopodia helianthoides*), green sea urchins (*Strongylocentrotus droebachiensis*) and sculpins (family Cottidae) arrived on the structures via immigration. By September 1997, small clumps of green algae and hydroids were growing on most of the structures, and filamentous red algae were common on the WB structures. Densities of epibenthos were lower inside the breakwater than outside. By December, the structures had been colonized by encrusting bryozoans, decorator crab (*Oregonia gracilis*), RKC, calcareous tubeworms, and nudibranchs (*Flabellina fusca*). In March, red algae (*Palmaria* sp.), *Laminaria* sp., tunicates (probably *Molgula* sp.), and hydroids were abundant. Filamentous red algae obscured the sheltered sediments inside the breakwater, but were absent outside the breakwater. By June, piling tops were once again covered with green algae, and helmet crab (*Telmessus cheiragonus*), hermit crab (*Pagurus* sp.), and RKC were common on the structures.

DISCUSSION

Our data demonstrate that log piling structures may serve as potential habitats for juvenile RKC. Numbers of crab on the structures were two orders of magnitude greater than on the adjacent seafloor. As a result of this work, we recommended to the USACE that new dock structures in the Kodiak area be built with pilings rather than sheet-metal bulkheads with backfill, as proposed by some developers. Use of pilings preserves the underlying seafloor substratum that would be covered by fill, and adds hard vertical structure useful to crab and other fauna. We cannot recommend that piling structures be deployed to mitigate for habitat loss at this time for several reasons. First, the reason why juvenile RKC are attracted to pilings is still not understood, though settlement among fouling organisms seems most likely. Second, pilings have limited surface area and low fractal dimension; that is, they are devoid of highly complex interstitial spaces, which is apparently the structural feature that makes various natural and artificial habitats attractive to juvenile RKC (Stevens & Kittaka 1998 and Stevens 2003). The relationship between the scale of refuge spaces and the range of body sizes is an important factor in survival of reef-associated decapods (Eggleston et al. 1992). If habitat enhancement is deemed worthwhile for future research, then other types of structures might be more effective by providing a greater variety of interstices in a more compact structure. Furthermore, wooden pilings do not last long in a marine environment unless treated with toxic chemicals, and steel or concrete pilings may not attract the same fouling community. Moreover, in this study we evaluated only one kind of structure; better structures might include crushed rock or gravel, or specifically designed man-made substrata. It is possible that the new breakwater provides more habitat of better quality than the original sedimentary substratum that it replaced.

In our study, RKC were more abundant at a site (OB) that was exposed to prevailing weather and current, and less abundant at a nearby site (IB) protected behind a large breakwater, or at the head of Womens Bay, several kilometers from open water. This distribution could result from recruitment processes involving the transport of larvae by ocean currents until they reach suitable exposed habitat sites. As more larvae settle on exposed sites, fewer would remain in the water to settle at protected sites. The breakwater and its many crevices may also have "filtered" out many larvae prior to

their arrival at the IB site. This hypothesis could also account for the higher numbers of RKC on the southernmost habitats within each pair. At each site, exposure to the open ocean decreased, and distance from it increased, along an axis from south to north. The abundance of infaunal polychaete tubes at the IB site is indicative of sheltered habitat, whereas lack of their presence at the OB site was probably the result of wave action and current scour. RKC probably arrived on the structures by settlement as postlarvae during the late summer and fall of 1997, but were too small to be seen by divers until December. Observed numbers of RKC increased through March 1998, then declined the following summer. By that time, the earliest arrivals were 15 mo old and 15–20 mm CL. At that size, they are less vulnerable to predation, so may have emigrated from the structures. Newer recruits either did not replace them at the same rate, or were not yet large enough to be seen by divers. One of the most important species of the epibenthic community are hydroids because they are important habitat for newly settled RKC glaucothoe (postlarvae), which choose them over alternative habitats due to their complex 3-dimensional structure (Stevens 2003). Hydroids were abundant among artificial collectors made of onion sacs stuffed with monofilament line (Donaldson et al. 1992 and Blau & Byersdorfer 1994), and may be one reason that glaucothoe settle there en masse. Hydroid colonies do not develop until late summer, and their presence on the pilings and buoy lines may attract settling RKC glaucothoe to the pilings. However, hydroids were not highly abundant when the first recruits began to appear, and most crab were observed on bare wood.

Biologic structures are important settlement habitats for juvenile RKC and are practically the only location where they are found in many parts of their geographical range, such as the Bering Sea, where physical structure is scarce. This distribution is the result of habitat selection by settling postlarvae (glaucothoe) rather than of predation. During their first year of life, juvenile RKC are associated with sponge and bryozoan colonies (Sundberg & Clausen 1977), mussel and hydroid colonies (see photo in Stevens 2003), stalked ascidians and polychaete tubes (Stevens & MacIntosh 1991), and shell debris and cobble (McMurray et al. 1986 and Loher & Armstrong 2000). Glaucothoe will settle in large numbers on various types of artificial collectors (Donaldson et al. 1991 and Blau & Byersdorfer 1994). In the laboratory RKC glaucothoe prefer structurally complex habitats, whether artificial (aquarium filter material) or biologic (hydroids and complex red algae), to those with less structure (gravel) and will not settle on structure-less open sand (Stevens & Kittaka 1998 and Stevens 2003). Selection for such habitats is probably an adaptive response to high predation levels. At sizes of 10–15 mm CL, RKC are often observed "hitch-hiking" on sea stars (Dew 1990). At sizes >25 mm CL, RKC start to exhibit aggregative (podding) behavior (Powell & Nickerson 1965 and Dew 1990).

Crab and lobsters are attracted to, and use, various artificial habitats. In Chile, *Cancer edwardsi* and *Homalaspis plana* use the hollow spaces in artificial reefs made of concrete blocks (Jara & Cespedes 1994). Numbers of both species increased significantly on the reef and in quadrat samples taken from the surrounding substratum, in contrast to our data, which showed virtually no RKC present on surrounding substrata. Adult stone crab *Menippe* sp. were more abundant among concrete block reefs spaced at 60 m intervals than among those spaced at 2 m intervals, and abundance was strongly seasonal (Frazer & Lindberg 1994). Stone crab apparently arrived by immigration as adults and foraged among the surrounding substratum, in contrast to RKC that settle on pilings as

postlarvae, and were rarely observed "off structure". Reefs made of cemented coal-ash were used by spider crab *Maja squinado*, velvet swimming crab *Liocarcinus puber*, and European lobster *Homarus gammarus*, the latter of which were predominantly adults, indicating that recruitment occurred through immigration rather than by settlement (Jensen et al. 1994). Caribbean spiny lobster *Panulirus argus* are attracted to "casitas" consisting of concrete blocks (Lozano-Alvarez et al. 1994), or concrete over a PVC frame (Eggleston et al. 1992). Despite the presence of crab and octopus, artificial shelters may reduce predation on small juvenile lobsters, and thus increase production of that sizegroup (Eggleston et al. 1992). In Delaware Bay, the biomass associated with concrete artificial reefs was 2 to 3 orders of magnitude greater than that of the surrounding substratum, although no large decapods were observed there (Foster et al. 1994 and Steimle et al. 2002).

Population enhancement is probably feasible for commercially valuable decapods like spiny and American lobster because their abundance is limited by the availability of their preferred habitats. Postlarval spiny lobsters settle preferentially in clumps of red algae (*Laurencia* sp.) (Herrnkind & Butler 1986). Enhancement of natural habitat (algal clumps) or addition of artificial shelters (concrete blocks) is an effective way to increase the abundance of juvenile lobster, whereas seeding with postlarvae or juveniles is not effective

(Butler & Herrnkind 1997 and Herrnkind et al. 1997a). Enhancement of natural substrata with gravel plots caused densities of postlarval American lobsters (*Homarus americanus*) to increase by a factor of 10, whereas supplemental postlarvae declined by a factor of 5 (Wahle 1991). At present, there is no convincing evidence that RKC populations are limited by lack of available settlement habitat, so population enhancement by the addition of artificial habitats may not be effective for this species. Further research on settlement behavior of postlarval RKC, and shelter use by juveniles, both in the laboratory and in their natural environment, is warranted before enhancement of habitat or populations is undertaken with this species.

ACKNOWLEDGMENTS

This project was partially funded by the United States Army Corps of Engineers under MIPR Nos. E86954046-0001 and F12961362-0001. The piling structures were built and installed by Majdic and Sons, Inc. The authors thank W. E. Donaldson for assistance with diving surveys, I. Vining for help with statistical analysis and interpretation, and C. Armistead for production of maps. The manuscript benefited greatly from reviews by R. S. Otto, A. Stoner, and R. Stone.

BIOLOGICAL CONTROL OF AQUARIUM PEST ANEMONE *AIPTASIA PALLIDA* VERRILL BY PEPPERMINT SHRIMP *LYSMATA* RISSO

ANDREW L. RHYNE*, JUNDA LIN, AND KATHIE J. DEAL**

Department of Biological Sciences, Florida Institute of Technology, Melbourne, Florida 32901

ABSTRACT Caridean shrimp in the genus *Lysmata* Risso are widely traded in the aquarium hobby industry. Peppermint shrimp *Lysmata* spp. have been used to control the brown (glass) anemone, *Aiptasia pallida* Verrill, a significant pest in the aquarium environment. A study was conducted to quantify the ability of two peppermint shrimp in controlling *A. pallida*. *Lysmata* sp. (Haiti variety) tended to have a higher consumption rate of sea anemone than *Lysmata* sp. (Florida Gulf Coast variety). Shrimp in a group tended to have a lower consumption rate per shrimp than individual shrimp in both species, but were capable of preying upon larger anemones. Larger (euhermaphrodite-phase) *Lysmata* (Florida Gulf Coast variety) had a higher rate of sea anemone consumption than that of smaller (male-phase) shrimp.

KEY WORDS: *Aiptasia pallida*, anemone, *Lysmata*, peppermint shrimp, predation

INTRODUCTION

Species of caridean shrimp *Lysmata* are commonly traded in the marine aquarium industry due to their striking coloration, beneficial symbiotic relationships, and quick acclimation to a captive environment. Many *Lysmata* species also feed on parasites of fish (Van Tassel et al. 1994; but see Spotte 1998), and therefore play an important role in the natural and aquarium environments.

The cleaner shrimps *L. amboinensis* De Man, *L. grabhami* Gordon, and *L. debelius* Bruce are revered for their ability to clean fish and their brilliant coloration, therefore command a high market price. Peppermint shrimp, several species of *Lysmata* with red or maroon stripes along the entire length of their translucent bodies, are not as brightly colored. However, they are in high demand for their apparent ability to control the common marine aquarium pest anemone *Aiptasia pallida*. Though the unit price is much less than that of *L. amboinensis*, *L. grabhami*, and *L. debelius*, the total volume sold annually greatly exceeds that of any other shrimp in the marine aquarium industry. Although peppermint shrimp are marketed under the name *L. wurdemanni* Gibbs, the vast majority of shrimp sold are in fact a novel species misidentified as *L. rathbunae* Chace (Rhyne 2002, Rhyne & Lin, in preparation). There are clear morphologic and some distribution differences, evidences of reproductive incompatibility and species-level genetic differences in the group. This confusion has resulted in unreliable reports of the most effective species for controlling *A. pallida*. Another unique feature of *Lysmata* species is their reproductive system, protandric simultaneous hermaphroditism (Bauer 2000), in which shrimp first mature as males and then change to simultaneous hermaphrodites. A proportion of the shrimp, influenced by group size, may remain as males (Lin & Zhang 2001).

Brown (glass) anemone *Aiptasia pallida* (Aiptasiidae) is a common pest in marine aquariums. They are commonly found in shallow and nutrient-rich waters along the subtropical and tropical Atlantic coasts. The brown color is caused by a unicellular symbiotic zooxanthae, *Symbiodinium microadriaticum* Freudenthal, which allows the anemone to thrive in highly illuminated environments (Trench 1993), including the marine reef aquariums. *Aiptasia* rapidly reproduce asexually by pedal laceration (budding from their pedal disc) (Hunter 1984). When it occurs in dark places, *A.*

pallida is not brown due to loss of zooxanthae, but rather a pure pallid white, hence the second half of its Latin name.

Stinging nematocysts within the anemone tentacles contain the venom beta phospholipase A2 and are used to stun prey or defend against potential predators (Grotendorst & Hessinger 2000). In the aquarium, these anemones harm both soft and hard corals and other sessile invertebrates, causing irritation and eventual death. The transparency and cryptic nature of *Aiptasia* results in its regular introduction into the marine aquarium from live rock or corals. *Aiptasia* cannot be eliminated by regular cleaning of aquarium. Many aquarium owners attempt to crush the anemones, which often promotes their proliferation and colonization in other areas of the tank. *Aiptasia* is commonly eliminated chemically and biologically. Chemical elimination is effective, but requires the laborious introduction of toxic injections directly into the oral disc of each anemone. Biologic control via anemone's natural predators eliminates the use of toxins. The nudibranch *Berghia verrucicornis* Costa (e.g., Carroll & Kempf 1990), butterflyfish (*Chelmon rostratus* Linnaeus and *Chaetodon kleini* Bloch), and peppermint shrimp are commonly used as successful natural predators of *Aiptasia*. However, there is no scientific study to quantify the effectiveness of such control.

The purpose of this study is to document the predation of two peppermint shrimp species, *Lysmata* sp. (Haiti variety) and *Lysmata* sp. (Florida Gulf Coast variety) on *A. pallida*. Though both shrimp are novel species, they are both commonly traded as *L. wurdemanni* Gibbs.

MATERIALS AND METHODS

The experiments were conducted at the Aquaculture Laboratory, Florida Institute of Technology, in 2002. *Aiptasia pallida* specimens were obtained from a local aquarium store and cultured in a 40-L tank. Anemones were fed live *Artemia* nauplii under constant light for 60 days and allowed to asexually reproduce on the glass walls of the aquarium. A razor blade was used to gently scrape the pedal disc base of the anemones, and the anemones were then placed on the rough surfaces of ceramic tiles. Each tile (11 × 11 cm) was carefully placed in a 10-L aquarium, and anemones were allowed to adhere to the tiles for a minimum of 24 h. Location of anemones on the tiles was haphazard due to the natural movement of anemones during reattachment.

Two species of peppermint shrimp, *Lysmata* sp. (Florida Gulf Coast variety) (collected from north of Tampa Bay) and *Lysmata*

**Present address: Department of Marine and Environmental Systems, Florida Institute of Technology, Melbourne, Florida 32901.

sp. (Haiti variety, collected from Haiti) were tested as anemone predators. The Florida Gulf Coast variety used in the current study was referred to as "*L. wurdemanni*" in some past studies (Zhang et al. 1998a, Zhang et al. 1998b). These shrimp do not conform to any current species definition, but are popularly (and mistakenly) referred to as *L. rathbunae* (see Debelius 2001 for photographs). We will refer to this species as *Lysmata* (gulf) in this paper. The Haiti variety was incorrectly recorded as *L. wurdemanni* by Holthuis (1959) and was referred to as such by Lin and Zhang (2001), and will be referred to as *Lysmata* (Haiti). This shrimp has pink gonads and a carmine red transverse stripe on the third abdominal segment, whereas *Lysmata* (gulf) has green gonads, a dark crimson telson, and does not have a transverse pigment stripe on the third abdominal segment. Both novel species tested are currently being described as part of a review of the peppermint complex found in the Western Atlantic (Rhyne and Lin, in preparation).

Test shrimp were maintained in a recirculating system. Each shrimp was placed into a marked container and fed frozen adult *Artemia* once daily in the afternoon after anemone feeding trials. Salinity and temperature were maintained at 35 and 26 C, respectively, for all the experiments.

To compare the consumption rates of the sea anemones (5–10 mm in oral disc diameter) by the two shrimp species, nine replicate shrimp of *Lysmata* (gulf) and *Lysmata* (Haiti), respectively, that had not previously fed on *Aiptasia* were used. Total length (TL) of each shrimp was measured. A single shrimp was placed into an enclosure within a 10-L aquarium that contained a tile with 9 to 11 anemones and allowed to acclimate for 15 min before being released into the aquarium. The time between release and each feeding and total number of anemones consumed were recorded. The shrimp was observed until all the anemones were eaten or for 24 h. An additional experiment was conducted to examine the feeding rate and behavior if multiple shrimp were present in an aquarium. Four groups (two for each species) of five shrimp of similar sizes were used. Each group was placed in a 10-L aquarium with a tile of 10 anemones. Again, the shrimp were confined to a holding pen and allowed to acclimate for 15 min prior to being released. The time from the shrimp's release to each feeding was recorded. The shrimp was allowed to feed until all the anemones were consumed.

To test the effect of shrimp size on its ability to feed on sea anemones, six large euhemaphrodite-phase and eight small male-phase *Lysmata* (gulf) were introduced individually into a 10-L aquarium with sea anemones (5–10 mm oral disk diameter) attached on a single tile. There was an average (\pm SD) of 14.8 (\pm 2.2) and 9.6 (\pm 3.1) anemones for each large and small shrimp, respectively. Each shrimp was confined to a holding pen and allowed to acclimate to the test aquarium conditions for 15 min prior to release. The number of sea anemone consumed was recorded after 24 h.

RESULTS

The average (SD) TL of *Lysmata* (gulf) and *Lysmata* (Haiti) was 24.1 (4.0) and 23.3 (5.2) mm, respectively. One shrimp of each species did not consume any anemone in 24 h. Excluding these two nonfeeding shrimp, an average (SD) of 9.1 (0.8) anemones was consumed by *Lysmata* (Haiti) in an average (SD) of 73.1 (26.8) min; and an average (SD) of 6.1 (2.4) anemones was consumed by *Lysmata* (gulf) in an average (SD) of 129.3 (78.9) min. The average (\pm SD) consumption rate of *Lysmata* (Haiti) (10.1 \pm 9.5 per h) is not significantly higher than that of *Lysmata* (gulf) (6.8 \pm 12.1 per h), due to large variations. The large variation in each species is due to one "outlier." If the "outlier" is removed

from each species, the average (\pm SD) consumption rate of *Lysmata* (Haiti) (6.8 \pm 1.6) is significantly (*t* test, $P < 0.05$) higher than that of *Lysmata* (gulf) (2.5 \pm 1.3). *Lysmata* (gulf) also had a significantly (*t* test, $P < 0.05$) longer average (\pm SD) response time (10.9 \pm 10.4 min) (from release to first feeding) than that of *Lysmata* (Haiti) (2.3 \pm 3.7 min).

The average (SD) TL of the first group of *Lysmata* (Haiti) was 18.0 (2.1) mm and it took the shrimp 48 min to consume the 10 anemones. The average (SD) TL of the second group of *Lysmata* (Haiti) was 19.0 (2.2) mm, and it took the shrimp 78 min to finish the 10 anemones. For *Lysmata* (gulf), the average (SD) TL of the first group was 22.0 (2.1) mm, and it took the shrimp 90 min to consume the 10 anemones. The average (SD) TL of the second group was 20.5 (4.1) mm, and it took the shrimp 31 min to consume the 10 anemones.

Large individuals (average \pm SD, TL = 41.0 \pm 3.0 mm) of *Lysmata* (gulf) consumed an average (SD) of 12.8 (4.3) anemones [out of 14.8 (2.2) offered] in 24 h, significantly (*t* test, $P < 0.05$) higher than that consumed [5.4 (4.3) anemones out of 9.6 (3.1) offered] by the small shrimp (average \pm SD, TL = 19.9 \pm 1.6 mm) during the same time period.

DISCUSSION

Both *Lysmata* species are capable of controlling *Aiptasia pallida*. *Lysmata* (Haiti) tended to have a higher predation rate and shorter response time than *Lysmata* (gulf). In *Lysmata* (gulf) at least, larger (euhemaphrodite-phase) shrimp consumed more anemones than smaller (male-phase) shrimp. Shrimp in a group tended to have a lower consumption rate per shrimp than individual shrimp. This may be a result of social interactions among the shrimp. Group feeding was not observed as cooperative, but competitive. In most cases, only one shrimp in a group was observed feeding on a small anemone at a time. However, a group of shrimp would feed on large anemones together and were able to consume larger anemones than an individual shrimp (unpublished data). Group feeding appeared to be cooperative for feeding on large anemones and competitive for feeding on small ones.

When attacking anemones, shrimp were prone to be stung with nematocysts and usually chose smaller, less harmful anemones. Peppermint shrimp appear to locate randomly the first anemone. After consuming the first anemone, the shrimp were observed readily seeking out other prey. The consumption of the first anemone appeared to invoke a feeding response. A shrimp would normally repeatedly approach the anemone until the anemone withdrew its tentacles. Then the shrimp would begin to consume voraciously the anemone. Some shrimp were observed making predation attempts, but were never successful. These shrimp may have molted recently, and their exoskeleton may be more sensitive to nematocysts (personal observation).

We observed that even satiated shrimp (after being fed with *Artemia* nauplii for an hour) would attempt to attack the anemones, but rescinded after being stung by the nematocysts. After a period of 24 h, the shrimp would successfully prey on anemones. While this study does not address the ability of shrimp to eat anemones over 10 mm oral disc diameter, both large shrimp (>3 cm TL) and groups of three to five shrimp have been observed to consume large (20 mm oral disc diameter) anemones (unpublished data).

EFFECTS OF SALINITY AND DIETARY CARBOHYDRATE LEVELS ON GROWTH AND ENERGY BUDGET OF JUVENILE *LITOPENAEUS VANNAMEI*

XINGQIANG WANG, SHEN MA,* SHUANGLIN DONG AND MEI CAO

Mariculture Research Laboratory, Fisheries College, Ocean University of China, Qingdao, 266003, People's Republic of China

ABSTRACT The culture of *Litopenaeus vannamei* in low-salinity waters is now popular in many regions of the world. A 6 × 3 factorial experiment was conducted to determine the effects of salinities (tap water, 1‰, 2‰, 4‰, 8‰, and 16‰) and dietary carbohydrate levels (15.47%, 29.15%, and 41.00%) on survival, growth, food consumption, food efficiency, absorption efficiency, and energy budget of juvenile *L. vannamei*. The results showed that no shrimp survived in tap water at the end of the experiment irrespective of dietary carbohydrate (CBH). At each dietary CBH level, the specific growth rate (SGR), food consumption, and food efficiency generally increased with increasing salinity within the range of 1–16‰. At salinities of 1‰, 2‰, 4‰, 8‰, and 16‰, optimal CBH levels corresponding to maximum SGR decreased with increasing salinity and were 29.87%, 27.59%, 26.85%, 26.25%, and 22.29%, respectively. At 1–8‰, the percentage of consumed energy deposited in growth (%C) was significantly higher in shrimps fed 29.15% CBH as compared with other treatments, whereas at 16‰, the significantly higher value was in those fed 15.47% CBH.

KEY WORDS: *Litopenaeus vannamei*, salinity, carbohydrate, growth, energy budget

INTRODUCTION

The shrimp-farming industry is currently experiencing major crop losses due to disease outbreaks sometimes associated with the deterioration of water quality, which makes the establishment of saltwater ponds economically risky. Instead, the culture of penaeid shrimp in low-salinity waters, which not only provides a cost-effective solution to prevalent disease problems but also improves the use of saline-alkaline land waters, is now popular in many regions of the world (Bray et al. 1994; Dong 2003). The Pacific white shrimp *Litopenaeus vannamei* (Boone, 1931) possesses the ability to tolerate low salinities. Recently, there has been increasing interest in the culture of this species in low-salinity waters or fresh water (Saoud et al. 2003), for which information is required on the effects of salinity on performance, principally growth and survival. A reduction in salinity may modify the osmotic and ionic balances in shrimp. To recover the normal balances, the shrimp may have to expend a considerable amount of energy, resulting in less energy to spare for growth (Bindu & Diwan 2002; Zhang & Dong 2002).

In general, glucose is one of the main energetic substrates for general metabolic processes in crustaceans (Hu 1958). In a recent study, Rosas et al. (2000) reported that *Litopenaeus stylirostris* can use the gluconeogenesis pathway according to dietary carbohydrate availability, with a higher gluconeogenic activity in shrimps fed diets containing comparatively low amounts of carbohydrate and low or no gluconeogenic activity in shrimps fed diets containing more than 20% carbohydrate. This better efficiency of using carbohydrate for routine metabolism, thus liberating protein for tissue aggregation, was also reported in *L. vannamei* (Dokken 1987), *Penaeus monodon* (Alava & Pascual 1987), and *Penaeus indicus* (Ali 1982).

Taking into account the energy consumption required for osmoregulation of *L. vannamei* adapting to low salinity conditions (Bindu & Diwan 2002), it is possible that carbohydrate metabolism adaptation takes place. This study was designed to determine the effects of tap water (about 0.2‰ salinity) and low salinities (1‰, 2‰, 4‰, 8‰, and 16‰) on growth of juvenile *L. vannamei* fed

three levels of dietary carbohydrates (15.47%, 29.15%, and 41.00%), together with an analysis of the bioenergetic mechanisms involved.

MATERIALS AND METHODS

Diet Preparation

Three approximately isoenergetic diets were formulated, containing 15.47%, 29.15%, and 41.00% of carbohydrate. The diets were prepared by mixing dry ingredients and water (2:1, w/w), and pellet-type diets were produced through a meat grinder with a 1.6 mm die. The diets were then oven-dried (70°C for 12 h) to 6–7% moisture and stored at 4°C until used. The formulation and proximate composition of the experimental diets are shown in Table 1.

Source and Acclimation of Experimental Shrimp

The experiment was carried out at the Laboratory of Aquaculture Ecology, Ocean University of China, Qingdao, P.R. China. *L. vannamei* juveniles were obtained from Hainan Shrimp Breeding Farm, Hainan, P.R. China. The shrimp were initially held in six fiberglass tanks (200 × 80 × 60 cm) at 31‰ for three days and were acclimated to six salinity levels (16‰, 8‰, 4‰, 2‰, 1‰, and tap water) by lowering the salinity at a rate of 5‰ d⁻¹ by adding tap water (about 0.2‰ salinity).

Experimental Design

A two-factor factorial experimental design (6 × 3) with three replications per treatment was followed. A static-water system consisting of 54 aquaria (45 × 30 × 30 cm, water volume 35 L) with aeration was used. After 24 h feed deprivation, 48 shrimp with weight range from 0.625 g to 0.645 g were selected from the acclimating fiberglass tanks. From the 48 shrimp, three groups of four shrimps each were randomly sampled for analysis of initial energy content and nitrogen content at the corresponding salinity level. The remainder (36 shrimp) were randomly stocked into nine aquaria with each aquarium holding four shrimps. The experiment lasted for five weeks. Shrimp were hand-fed an excess ration twice daily (at 06:00 and 18:00 h) for each group. Each meal lasted approximately 2.5 h, and any uneaten food was collected and dried at 70°C. Twice a day, intact feces and molts were collected from

each aquarium, freeze-dried immediately, and held at 20°C until analyzed. For each aquarium, two-thirds of the water was replaced daily. During the experiment, dissolved oxygen was maintained above 6.0 mg/L, water temperature at 25 ± 0.5°C, pH from 7.7 to 8.2, and the photoperiod was 14L:10D.

Calculation of Data

Specific growth rate (SGR), food efficiency (FE_t), energy conversion efficiency (FE_e), and absorption efficiency (AE) were calculated as follows:

$$\text{SGR} = 100 \times (\ln W_2 - \ln W_1) / t$$

$$\text{FE}_t = 100 \times (W_2 - W_1) / C_w$$

$$\text{FE}_e = 100 \times (E_2 - E_1) / C_e$$

$$\text{AE} = 100 \times (C_w - F_d) / C_w$$

where W₂ and W₁ are the final and initial wet weights of the shrimp, E₂ and E₁ are the final and initial energy contents of the shrimp, C_w is the food consumption in dry weight, C_e is the consumed energy, F_d is the fecal production in dry weight, and t is the duration of the experiment.

The energy budget equation of *L. vannamei* juveniles can be defined through the construction of a budget in which the consumed energy (C) is partitioned between growth (G), respiration (R), excretion (U), feces (F), and exuviae (E), i.e., C = G + R + U + F + E. The gross energy contents of diet, shrimp, feces, and molt were measured with a 1281 Oxygen Bomb Calorimeter (Parr Instrument, Moline, Illinois). The initial energy contents of the

shrimp were assumed to be equal to the average energy value of the shrimp sacrificed at the beginning of the experiment.

Preliminary experiment indicated that nitrogen in *L. vannamei* juveniles was mainly excreted as ammonia, with only very small amounts of urea and uric acid that might be negligible. The excretory nitrogen is converted into energy using the equivalent of 24,830 J · g⁻¹ N for nitrogen excreted (Elliott 1976). Hence, the energy lost as U can be calculated using the equation:

$$U = (C_N - G_N - F_N - E_N) \times 24,830$$

where C_N, G_N, F_N, and E_N represent the nitrogen contents of diet, shrimp, feces, and molt, respectively. The nitrogen contents of diet, shrimp, feces, and molt were measured with a PE-240 element analyzer (Beijing NCS Analytical Instrument Company, Beijing, China). The initial nitrogen contents of the shrimp were assumed to be equal to the average nitrogen value of the shrimp sacrificed at the beginning of the experiment.

The energy lost as R can be calculated using the equation:

$$R = C - G - F - E - U$$

Statistical Analysis

Data from each treatment were subject to a two-way ANOVA. When overall differences were significant at less than the 5% level, Tukey's test was used to compare the mean values between individual treatments. The square-root transformation of the sine-arc before analyzing the values given in percentages was used. Statistical analysis was performed using SPSS (statistic package for social science) 10.0.

RESULTS

Growth

All shrimps survived at 4, 8, and 16‰, whereas no shrimps survived in tap water (about 0.2‰ salinity) at the end of the experiment, irrespective of dietary carbohydrate (CBH). Hence, analysis of the respective dependable variable of shrimps maintained in tap water was excluded from the experiment except for concerning the survival. Within the range of 1–2‰, the survival increased with increasing dietary CBH from 15.47% to 41.00%, and at each CBH level, the survival in shrimps maintained at 2‰ was slightly higher than those maintained at 1‰. At each dietary CBH level, the specific growth rate (SGR), food consumption (FC), and food efficiency (FE_t) generally increased with increasing salinity from 1‰ to 16‰, and the highest values were obtained in those maintained at 16‰ (Table 2 and Fig. 1).

A two-way ANOVA showed that salinity, dietary CBH, and the interaction between salinity and dietary CBH had significant effects on survival, SGR, FC, and FE_t, but none for absorption efficiency (AE). The relationship between SGR, FC or FE_t, salinity, and dietary CBH is shown in Table 3.

In the 16‰ groups, SGR and FC were similar in shrimps fed 29.15% and 15.47% dietary CBH, whereas those fed 41.00% dietary CBH exhibited a significantly lower value. In the 1–8‰ groups, SGR and FC in shrimps fed 29.15% dietary CBH were significantly higher as compared with other treatments (Fig. 1 and Table 2). The relationship between SGR and dietary CBH is shown in Table 4. Quadratic regression analysis indicated that the optimal CBH corresponding to maximum SGR decreased with increasing salinity from 1‰ to 16‰ and were 29.87%, 27.59%, 26.85%, 26.25%, and 22.29% at salinities of 1‰, 2‰, 4‰, 8‰, and 16‰, respectively.

Means in the same column sharing a common superscript letter were not significantly different ($P > 0.05$) as determined by Tukey's test.

IW, initial weight; FW, final weight; FC, food consumption; FE_f, food efficiency; AE, absorption efficiency; values are means of three groups of *L. vannamei* juveniles, with 4 shrimp per group ($n = 4$).

Energy Budget

The pattern of energy allocation varied with salinity and dietary CBH, in which 67.90–80.24% of consumed energy was lost through respiration, 7.25–18.14% invested in growth, 5.21–5.99% for feces, 3.87–8.73% for excretion, and only 0.69–0.73% for exuviae (Table 5). At each dietary CBH level with increases of salinity within the range of 1–16‰, the consumed energy and the percentage of consumed energy invested in growth (%C) exhibited increasing trends while that lost in respiration and excretion (%C) exhibited decreasing trends. At 16‰, the percentages of respiration and excretion (%C) were lowest of all while the consumed energy was highest of all; thus energy conversion efficiency was highest of all.

A two-way ANOVA showed that salinity, dietary CBH, and the interaction between salinity and dietary CBH had significant effects on growth, respiration, and excretion (%C), but none for feces and exuviae (%C). The relationship between growth, respiration or excretion (%C), salinity, and dietary CBH is shown in Table 3.

At 1–8‰, the percentage of consumed energy deposited in growth (%C) was significantly higher in shrimps fed 29.15% CBH as compared with other treatments, whereas at 16‰, the significantly higher value was in those fed 15.47% CBH (Table 5). The relationship between growth (%C) and CBH is shown in Table 4. Quadratic regression analysis indicated that the optimal CBH corresponding to maximum percentage in growth (%C) decreased with increasing salinity from 1‰ to 16‰ and was 29.36%, 26.75%, 26.50%, 26.40%, and 18.43% at salinities of 1‰, 2‰, 4‰, 8‰, and 16‰, respectively.

DISCUSSION

Salinity Effect on Growth of *L. vannamei* juveniles

A reduction in salinity can significantly affect the survival and growth of penaeid shrimps, although they possess the ability to tolerate low salinities (Huang 1983, Bray et al. 1994). Galli & Stern (1998) reported that the survival of *L. vannamei* was drastically reduced when salinity decreased below 0.18‰. Bray et al.

Figure 1. The effects of salinity and dietary carbohydrates (CBH) on specific growth rate (SGR) of *L. vannamei* juveniles; values are means of three groups of *L. vannamei* juveniles, with 4 shrimp per group ($n = 4$); means with different letters are significantly different ($P < 0.05$), and bars indicate standard errors of the means.

erate very low salinities. It was apparent from the experiment, however, that salinity had significant effects on both growth and food efficiency. At each dietary carbohydrate level, the maximum specific growth rate and food efficiency were obtained in shrimp maintained at 16‰ and diminished with a reduction in salinity; the shrimps maintained at 1–2‰ exhibited significantly lower values. Hence, at salinities ≤16‰, decreasing salinity significantly affected the growth rate of *L. vannamei* juveniles and even endangered their survival.

The growth rate of the shrimp seems to have a direct relation with food consumption, changes of which may reflect the adaptation to various environmental conditions. Previous studies had shown that holding penaeid shrimps at salinities near isosmotic points could result in an increase of food consumption (Staples & Heales 1991). Rosas et al. (2001a) reported that *L. vannamei* juveniles maintained at 15‰ salinities consumed 1.69 times more food than those at 5‰. Similarly, in the present study, food consumption generally increased with increasing salinity within the range of 1–16‰ with the maximum value at 16‰, which coincided with the salinity at which the highest specific growth rate was observed, indicating that at salinities ≤16‰, holding *L. vannamei* juveniles at salinities closer to isosmotic points could result in increased appetite.

The isosmotic point for penaeids ranged from 23 to 30 ppt (Dall 1981; Castille & Lawrence 1981). It is generally believed that shrimps near the isosmotic point expend the least energy on respiration and excretion, and so they exhibit the best growth rate and the most efficient energy conversion (Panikkar 1968). By contrast, when shrimps are under anisomotic conditions, additional energy is required to meet the osmotic adjustments, which generally increase as a function of deviations in salinity from the isosmotic zone; that is, when the concentration gradient between ambient salinity and body fluids increases, more energy is expended for recovery of homeostasis and, as a result, less energy is available for growth (Zhang & Dong 2002; Bindu & Diwan 2002). In the present study, as the range of salinity tested deviated from the isosmotic point, the energetic demand on maintaining homeostasis, i.e., the percentages of energy lost to respiration and excretion (C%), increased with decreasing salinity from 16‰ to 1‰.

The results obtained in our work provide evidence that the growth differences between salinities are primarily the consequence of variations in both food consumption and energy allocation. Food consumption and energy gain (the percentage of energy invested in growth, C%) of *L. vannamei* juveniles appeared to increase with increased salinity within the range of 1–16‰, whereas total metabolic expenditure (the percentages of energy lost to respiration and excretion, C%) displayed inverse trends with salinity. Thus, the enhanced growth of *L. vannamei* juveniles with increasing salinity from 1‰ to 16‰ was mainly due to the significantly increased food consumption associated with the significantly decreased proportion of energetic cost for osmotic regulation. At 16‰, the food consumption was highest of all while the proportion of energy losses was least of all, and consequently, the growth rate was highest of all. By contrast, previous investigations suggested that the depression of growth for the shore crab *Carcinus maenas*, the common carp *Cyprinus carpio*, and the blue crab *Callinectes sapidus* under hypo-osmotic stresses could not be explained with enhanced metabolic demands; rather, this result was a consequence of a significantly reduced assimilation capability (Guerin & Stickle 1992, 1995; Wang et al. 1997; Anger et al. 1998). In the present study, salinity had no significant effects on

absorption efficiency and the percentage of fecal production (%C), indicating the different bioenergetic mechanisms by interspecies.

Carbohydrate Effect on Growth of *L. vannamei* Juveniles at Low Salinities

Carbohydrate is considered the most economical source of dietary energy in penaeid shrimp. Previous investigations on a variety of penaeid species indicated an improved growth on diets with an adequate dietary carbohydrate supply. Ali (1982) reported that the survival, growth, and food conversion efficiency of juvenile *P. indicus* increased with an increase in the dietary carbohydrate level from 10–40%. Rosas et al. (2001b) reported that the maximum growth rate for *L. vannamei* juveniles occurred between 6% and 23% of dietary carbohydrate.

It is generally believed that more energy is expended for osmoregulation by aquatic animals subjected to hypo-osmotic environments as compared with those maintained under isosmotic conditions (Panikkar 1968). Hence, we speculated that maximizing the carbohydrate content relative to protein in diets might promote the growth of penaeid shrimp maintained at low salinities, based on

the assumption that diets were formulated to be isoenergetic. In the present study, dietary carbohydrate had significant effects on growth, food consumption, and energy gain (the percentage of energy invested in growth, C%). At 1–8‰, the specific growth rate in shrimps fed 15.47% dietary carbohydrate was significantly lower than those fed 29.15% dietary carbohydrate; by contrast, at 16‰, the specific growth rate in shrimps fed 15.47% dietary carbohydrate was not significantly different from those fed 29.15% dietary carbohydrate. The responses of food consumption and energy gain (C%) to dietary carbohydrate were similar to that of the specific growth rate. These results confirmed that carbohydrate was an important source of energy for *L. vannamei* juveniles maintained at low salinities, and an adequate level of carbohydrate provided in diets could not only significantly improve growth performance of *L. vannamei* juveniles, but also have a protein sparing action.

ABSTRACT This study describes the prevalence of a parasitic bopyrid isopod, *Parapenaeon consolidatum*, on *Metapenaeopsis dalei* and its effect on host growth and reproduction. The prevalence of *P. consolidatum* increased with shrimp size, from 27.3% at 5 mm CL to 68.4% at 16 mm CL. Lengths of female bopyrids and that of their hosts were positively correlated. This indicated that the bopyrid stays continuously with its host and is not detached when the host molts. Morphometric analyses indicated that parasitized male and female shrimp have slightly lower body weight and length than nonparasitized shrimp of the same carapace length. The gonadosomatic index was higher for nonparasitized than for parasitized female shrimp. Growth of the petasma, the copulatory organ of male shrimp, was significantly affected by the parasite.

KEY WORDS: *Metapenaeopsis dalei*, *Parapenaeon consolidatum*, growth, reproduction

INTRODUCTION

The kishi velvet shrimp, *Metapenaeopsis dalei* (Rathbun), is distributed throughout the coastal waters of Korea, Japan, and China in sandy muddy substrates at 30–130 m depth (Kim 1977, Hayashi 1992). With seasonal warming of the waters starting in April, the shrimp begin to migrate from deeper water to the coastal area. They are exploited commercially in Korea from April to October, using shrimp trawl and stow nets (Cha 1997). *Metapenaeopsis dalei* exhibit higher burrowing rates than other penaeid shrimp (Sakaji 1995). Owens (1987) reported that the bopyrid isopod *Parapenaeon consolidatum* Richardson is a parasite on *M. dalei* from Japanese waters. However, little is known about the effects of this parasite on growth and reproduction of its host.

Bopyrids live on shrimp, brachyurans, and anomurans and cause a conspicuous bulge of the branchiostegite (Dall et al. 1990). Owens and Glazebrook (1985) showed that bopyrids on penaeids grow with their hosts and have a similar longevity, although there is some loss of parasites as the prawns approach asymptotic length. Some studies hypothesized a relationship between a bopyrid and its host because of a highly positive correlation between the sizes of female bopyrids and their shrimp hosts (see Beck 1980; Schultdt & Rodrigues Capitulo 1985). Cash and Bauer (1993) reported that *Probopyrus paudallicola* (Packard) remain on and grow synchronously with *Palaemonetes pugio* Holthuis; video recording has shown that reproductive activities of the parasites are synchronized with host molting.

Both growth and reproduction of shrimps can be affected by bopyrids. Abu-Hakima (1984) showed that parasitized male *Penaeus semisulcatus* De Haan grew to the same size as nonparasitized females but that host reproduction was totally inhibited. She also showed that a petasma, the male copulatory organ, was not formed in parasitized male shrimp. Chu & Leong (1996) indicated that parasitized male and female shrimp have slightly lower average body weights than nonparasitized shrimps of the same carapace length. Dawson (1958) reported that in the Arabian Gulf, only

P. semisulcatus larger than 100 mm TL (total length) were parasitized with bopyrids. Mathews et al. (1988) found low parasite prevalence among *P. semisulcatus* of 14–18 mm CL (carapace length) by *Epipenaeon elegans* Chopra; prevalence increased up to a prawn size of around 28 mm CL, after which the rate fell, apparently because of loss of the parasite. Some bopyrid parasites alter the appearance or behavior of the host whereas others are asymptomatic.

This study provides additional information on the prevalence of *P. consolidatum* in relation to host size, the effects of bopyrid parasitism on the growth and reproduction of parasitized shrimp, and the relationship between the host shrimp and bopyrid breeding rate.

MATERIALS AND METHODS

Shrimps were collected monthly from September 1998 to June 2000 with a research shrimp beam trawl (mesh size: 9.3 × 9.3 mm) in waters around Yongchodo, South Korea (128°40'E, 34°30'N). The study area was sandy mud in the channel between Hansando and Yongchodo at 20–30 m depth. During this study, water temperature varied from 6.7 to 25.8°C (Fig. 1). Samples were fixed immediately in neutralized formaldehyde for 1–2 days and were then preserved in 70% alcohol.

Specimens were sorted and sexed. Parasitized shrimps were detected by an obvious deformation of their carapace. Bopyrids were removed, and the females were classified as ovigerous or nonovigerous. In the shrimp, carapace length (CL, from posterior orbital margin to the posterior edge of carapace in the mid-dorsal line) and body length (BL, from the tip of the rostrum to the end of the telson) of shrimp were measured with a caliper to the nearest 0.1 mm. Shrimp body weight (BW) was determined to the nearest 0.01 g after the shrimp was blotted dry. In males, the petasma length (PL, from the tip of the lobe to the end of the petasma) was measured to the nearest 0.01 mm under a dissection microscope. In parasites, body lengths (from the anterior margin of the head to the posterior margin of the pleotelson) of female (FPL) and male (MPL) bopyrids were measured under a dissection microscope to the nearest 0.01 mm.

The effects of the parasites on host log transformed BW, BL, and PL (reproduction) were determined statistically by analysis

Figure 1. Monthly variation of seawater surface temperature (line) and number of specimens (bars) at the sampling sites.

with CL as covariance (ANCOVA) using Minitab version 2.0 (Sokal & Rohlf 1995). Analyses were based on individuals with no visibly developed gonads (CL < 12.09 mm; Choi 2001), as gonad development alters the length-weight relationship of both female and male shrimp (Chu & Leong 1996).

RESULTS

Prevalence

A total of 2550 specimens of *M. dalei* were caught (Fig. 1). Females were consistently more abundant in all size classes; the overall proportion of females was 53.1% but varied with shrimp size. The proportion of females sharply increased from 50–100% for size classes >16 mm CL (Fig. 2). Forty-eight percent of both the 1360 female shrimp and the 1190 male shrimp were parasitized

Figure 2. Size-specific female sex ratio (line) and number of *Metapenaeopsis dalei* (bars) caught at Yongchodo from September 1998 to June 2000. Sex ratio = (number of female specimens/total number of specimens) \times 100.

by *P. consolidatum*. The smallest parasitized female and male shrimp were 4.21 mm and 4.72 mm CL, respectively. The largest parasitized female and male shrimps were 21.25 mm and 18.44 mm CL, respectively. Female prevalence increased from 28.6% at 5 mm CL to 62.3% at 10 mm CL, leveled off between 11 and 12 mm CL, and sharply increased from 37.5% at 12 mm CL to 90% at 16 mm CL. Male prevalence increased from 25% at 5 mm CL to 59.5% at 9 mm CL, decreased between 10 and 11 mm CL, and increased from 43.4% at 11 mm CL to 100% at 15 mm CL. Parasitism incidence for females and males >16 mm CL and >15 mm CL, respectively, dropped sharply (Fig. 3). Overall, parasitism occurred early in the life of the host and until shrimp reached 11 mm CL, prevalence was the same in both sexes. However, between 12 mm and 15 mm CL, prevalence among males was higher than among females.

Host-parasite Relationship

Female *P. consolidatum* filled most of and were tightly lodged within the host's branchial chamber, producing a characteristic bulge in the host's branchiostegite. Male parasites oriented perpendicularly to the female's body axis on the ventral side of the female's abdomen. Regression analysis showed a significant relationship between FPL and CL (Fig. 4). The relationship was similar for female and male hosts (ANCOVA intercept: $F = 3.08$, $df = 1,254$, $P = 0.081$). The relationship between FPL and MPL was also significant (Fig. 5).

Host Growth Rate Effects

CL-BL regression slopes for parasitized and nonparasitized shrimp were significantly different for female shrimp (ANCOVA: male, $F = 3.72$, $df = 1,39$, $P = 0.06$; female, $F = 11.31$, $df = 1,71$, $P < 0.05$) (Fig. 6). Also, parasitized and nonparasitized shrimp had significantly different CL-BW regression slopes (ANCOVA: male, $F = 5.13$, $df = 1,114$, $P < 0.05$; female, $F = 10.24$, $df = 1,153$, $P < 0.05$) (Fig. 7).

Figure 3. Size-specific prevalence (%) of the endoparasite *Parapenaeon consolidatum* on *Metapenaeopsis dalei* caught from Yongchodo from September 1998 to June 2000. Prevalence = number of parasitized specimens/total number of specimens \times 100.

Figure 4. Relationship between carapace length of *Metapenaeopsis dalei* and total length of its female parasite (*Parapenaeon consolidatum*) from Yongchodo between January and December 1999.

Host Reproduction Effects

There were no changes in the structure of the thelycum in parasitized female shrimps. In nonparasitized males, the petasma consisted of the typical complex of membranous folds and ridges in the endopodites of the first pairs of pleopods. In parasitized males, endopodites were only partially fused or more frequently were separate structures. The PL-CL regressions for nonparasitized and parasitized male shrimp had similar slopes (ANCOVA: $F = 2.56$, $df = 1,204$, $P > 0.05$) but different intercepts (ANCOVA: $F = 125.31$, $df = 1,205$, $P < 0.05$) (Fig. 8). Thus, the PL of parasitized male shrimp was smaller than that of nonparasitized male shrimp.

To investigate the influence of the bopyrid parasite on gonad development, the gonadosomatic index (GSI) of female shrimp

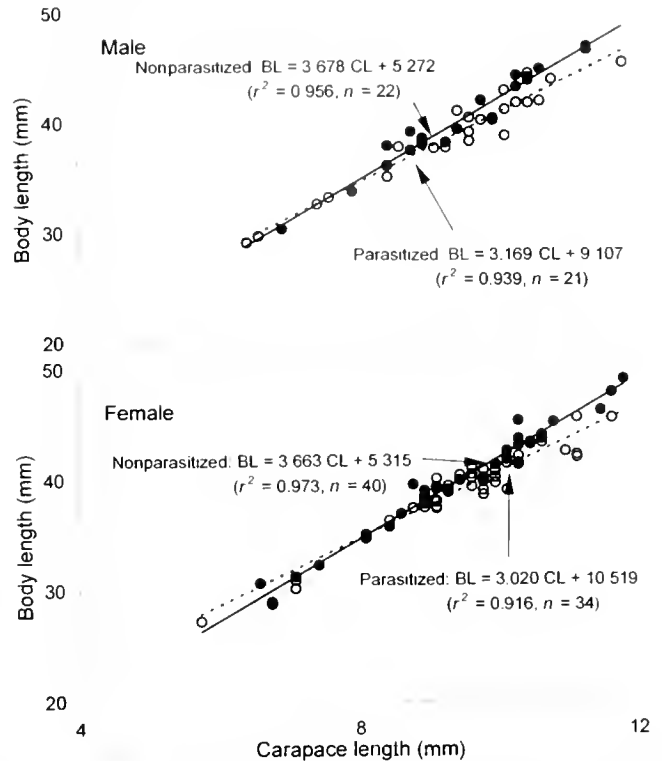

Figure 6. *Metapenaeopsis dalei* body length (BL) to carapace length (CL) relationships for parasitized and nonparasitized shrimp. Regression lines were calculated from the specimens caught from Yongchodo on November 1999. Open and solid circles represent parasitized and nonparasitized shrimp, respectively.

caught during the breeding season (July–August, Choi 2001) were compared with CL. GSI values of nonparasitized female shrimps were significantly larger than those of parasitized shrimps (Kruskal-Wallis Test: $H = 8.10$, $P < 0.01$) (Fig. 9).

Parasite Maturity

Size frequency distribution of female parasites is shown in Figure 10.

DISCUSSION

In this study, the 48% parasitism rate of *M. dalei* by the bopyrid *P. consolidatum* was much higher than the 0.24% reported for *Penaeus longistylus* Kubo parasitized by *Parapenaeon japonicum* (Thielemann) and *Parapenaeon prox. expansus* on Queensland's east coast (Courtney 1991). Prevalence fluctuated during the sampling year, as observed for other bopyrid-host pairs (Beck 1980, Somers & Kirkwood 1991). Seasonal fluctuations have been ascribed to differential migration patterns among parasitized and nonparasitized shrimp or to seasonal variations in the reproduction and mortality rates of hosts and parasites (Mathews et al. 1988; Torres Jordá & Roccatagliata 2002).

Roccatagliata & Lovrich (1999) reported that the prevalence of the parasite *Pseudione tuberculata* Richardson decreased with *Paralomis granulosa* (Jacquinot) size and suggested a high mortality rate for small parasitized *P. granulosa*. In contrast, we observed increasing parasitism in proportion with size for the smaller host size classes (3–9 mm CL), suggesting that *M. dalei* did not cause increasing mortality in the small size classes. We suggest the

Figure 5. Relationship between female parasite and male parasite (*Parapenaeon consolidatum*) total lengths on *Metapenaeopsis dalei* from Yongchodo between January to December 1999.

Figure 7. *Metapenaeopsis dalei* wet weight (WT) to carapace length (CL) relationships for parasitized and nonparasitized shrimp. Exponential growth curves were calculated from the specimens caught from Yongchodo on November 1999. Open and solid circles represent parasitized and nonparasitized shrimp, respectively.

decrease in prevalence between size classes 9 mm and 12 mm CL was due to a relatively higher host growth rate of these individuals during the study period. Choi (2001) reported that at these size classes, shrimp frequently molted during the summer. Somers &

Kirkwood (1991) showed that *P. semisulcatus* parasitized by *Epipenaeon ingens* Nobili may lose their bopyrids: of 22 parasitized prawns that were released, six had lost their bopyrids upon recapture two weeks later. Cash & Bauer (1993) gave further direct evidence of parasite loss in *P. pugio* parasitized by *P. pandalicola*. They noted that bopyrids were shed with the shrimp exuviae in three of the 112 moltings examined. Additional indirect evidence of parasite loss is from the size of maturity of female parasites, which begin spawning at 4–5 mm FPL (host size of ca. 9 mm CL). Cash & Bauer (1993) reported that *P. pandalicola* larvae escaped from the host, *P. pugio*, during the latter's molting period. They showed that epicaridium larvae were released from the host's branchial chamber several hours before the host molted. A de-

Figure 10. Size-frequency distribution of female parasite *Parapenaeon consolidatum* on *Metapenaeopsis dalei* caught from Yongchodo November 1999. Solid and open bars represent ovigerous and nonovigerous parasite females, respectively.

creasing parasitism with larger size classes of shrimp can also perhaps be explained by a shorter life span of parasitized shrimp versus that of nonparasitized shrimp.

The positive correlation of FPL of *P. consolidatum* with the CL of *M. dalei* (Fig. 4) suggests that the parasite attaches to small hosts and grows along with them. This should negatively affect host growth (Chu & Leong 1996). However, we found that with <8 mm CL size classes of parasitized shrimp, BL and WT averaged relatively larger on nonparasitized shrimp of the same CL. However, by the time they reached 8 mm CL, the ratios of BL and WT to CL were relatively similar for both groups of shrimp. This finding may be explained by two hypotheses. First, parasitized shrimp may initially consume more than nonparasitized shrimp and hence grow faster; the parasite may thus be influencing the behavior of the shrimp. Anderson (1977) reported that *P. pugio* parasitized by *P. pandalicola* ate more *Artemia salina* Linnaeus nauplii than nonparasitized shrimp. Second, *P. consolidatum* may preferentially select larger CL hosts at the time of infection, because a larger host might provide more space for bopyrid development and reproduction. The strategy of the parasite may thus be to select a host with the optimal growth and size. Either approach might be adaptive, because parasite size and fecundity are related to host size (see Baudoin 1975; Shearer 1977).

BL and WT of parasitized shrimp are smaller than with nonparasitized shrimps for >8 mm CL size classes. The increased breeding rate of female parasites on shrimp >8 mm CL may be indicative of a negative effect on shrimp by the parasite. Bopyrid isopods have evolved as branchial parasites on decapod crustacean hosts (cf., Markham 1975) and affect their host in a variety of ways through their high rate of ingestion of the host's hemolymph (Walker 1977). Nelson et al. (1986) showed that the energy expenditure of breeding bopyrid *Argeia pauperata* Stimpson females is more than that of its normal host, *Crangon franciscorum* Stimpson.

Parapenaeon consolidatum affects the genital growth of *M.*

dalei; the length of a parasitized shrimp's petasma is less than that on a nonparasitized shrimp. The length of the petasma normally increases directly with increasing CL (Burkenroad 1934). Some studies suggested that the petasma assists in the transfer of spermatophores to the female (Hudinaga 1942; King 1948). We suggest that in parasitized males, a smaller petasma length negatively affects sperm transfer and hence copulation success. In addition, our observation indicated that a few parasitized larger males had unfused or only a partly joined petasma. Dall (1958) defined male maturity of *Metapenaeus mastersii* (Haswell) (= *Metapenaeus bennettiae* Racek & Dall) by the presence of a fully developed petasma. Tuma (1967) reported that small *Penaeus merguensis* De Man males had a longitudinally constricted petasma on their pleonic endopodites; when mature, the end of endopodites had joined to form the petasma. Thus, *P. consolidatum* affects the growth of the petasma in *M. dalei*, which likely negatively affects male shrimp reproductive ability.

CONCLUSION

Our main conclusions are that *M. dalei* has an exceptionally high rate of parasitism by *P. consolidatum*. Parasitism proportion increased with host shrimp size. Selection of a larger host may provide more branchial chamber space for the parasite, or *M. dalei* may grow faster because of parasite induced hunger, because other studies have shown that parasitized shrimp eat more food than do nonparasitized shrimp. Because the parasite negatively effects growth of the host's genital organ and development of gonads, it may be reducing population fecundity because a large portion of the male population consequently cannot effectively reproduce.

THE EFFECT OF STARVATION ON REFEEDING, DIGESTIVE ENZYME ACTIVITY, OXYGEN CONSUMPTION, AND AMMONIA EXCRETION IN JUVENILE WHITE SHRIMP *LITOPENAEUS VANNAMEI*

ABSTRACT Juveniles of the white shrimp *Litopenaeus vannamei* were kept without food for between 0 to 15 days to evaluate the impact of starvation on physiologic state (oxygen consumption, poststarvation refeeding index, nitrogen excretion, and O:N ratio) and digestive enzymes activity. Physiologic changes were found after 6 days of fasting, and refeeding ability declined as a result. Nevertheless, the shrimp were able to survive 16 days without food. Starvation caused metabolism to drop progressively toward a basal level ($21 \text{ J} \cdot \text{h}^{-1} \cdot \text{g}^{-1}$) and a decrease in the rate of ammonia excretion, because of the catabolism of amino acids from soluble protein in the hepatopancreas. This decrease led to an increase in digestive enzymes specific activity (U/mg protein). But, expressed as total U, all digestive enzyme activities decreased in the absence of substrate from 0.016 to 0.007 U/hepatopancreas (HP) for α -amylase and 2.58 to 0.63 U/HP for total trypsin. *L. vannamei* juveniles showed a true physiologic adaptation mechanism to food deprivation: no changes in body weight but loss in hepatosomatic index, no exuviations, including the utilization of HP soluble proteins (a drop from 269 to 53 mg/mL). After 10 days, a neoglycogenic pathway and the corresponding tissue enzymes activities seemed enhanced, and the animals derived all energetic substrates mainly from protein (O:N ratio of 17) to cover their metabolic costs. Estimates of basal metabolism (Hem) from the routine respiration rate per day (from 361 to 725 $\text{J} \cdot \text{g} \text{ww}^{-1} \cdot \text{day}^{-1}$ through the 15-day starvation period), and loss of nonfecal energy (HxE) from the nitrogen excretion rate (varying from 39 to 57 $\text{J} \cdot \text{g} \text{ww}^{-1} \cdot \text{day}^{-1}$ during the same period) were used in a bioenergetic partition model of a fasting juvenile, which indicated that the energetic requirement to survive without feeding was in the range of 418 and 771 $\text{J} \cdot \text{g} \text{ww}^{-1} \cdot \text{day}^{-1}$ during the 15-day period of starvation.

KEY WORDS: digestive enzymes, *Litopenaeus vannamei*, metabolic rate, shrimp, starvation

INTRODUCTION

The Pacific white shrimp *Litopenaeus vannamei* is cultured in extensive, intensive, and semi-intensive systems and is, with *Litopenaeus stylirostris*, the most popular shrimp for aquaculture in Mexico and Central and South America. The state of Sinaloa on the northwest coast of Mexico, considered the most important agricultural producer in the country, has observed in recent years an important increase of aquaculture farms, from approximately 100 hectares of ponds in 1984 to 1850 hectares in 1998, with a growth rate of about 150 hectare/year. Nowadays, Sinaloa has more than 200 shrimp farms (about 75% of the national total) and produces around 10,000 tons yearly (65% of the national total) (Hernandez Cornejo & Ruiz Luna 2000).

The digestive gland is generally regarded as a major storage organ in decapods crustaceans (Allen 1971, Huggins & Munday 1968). The study of the digestive gland is of considerable interest because of its role in the accumulation and cyclic mobilization of reserves during the molting process, its contribution of nutrients to the ovary during vitellogenesis, the mobilization of its reserves during starvation, and its role in digestion and absorption. The level of the digestive enzymes in decapod crustaceans does not remain constant during the developmental cycles (Van Wormhoudt 1974) as a result of both external and internal factors. Among the external factors, the quantitative and qualitative variability of food is poignant.

Physiologic and biochemical effects of starvation have been

studied in several decapod species (Anger 1986, Cuzon et al. 1980, Cuzon & Ceccaldi 1973, Dall & Smith 1986, Wehrmann 1991), but little is known about the effects of prolonged food deprivation. Changes in biochemical composition during starvation have been reported in *Marsupenaeus japonicus* where there was a progressive suppression of metabolism compared with normally fed shrimp (Cuzon et al. 1980). The study found that the shrimp primarily used carbohydrates, then lipids to meet their energy requirement; proteins were significantly used only during the fourth week of starvation (Cuzon et al. 1980). In *L. vannamei* postlarvae, triacylglycerol provided energy during short periods of starvation whereas protein was used during prolonged starvation (Stuck et al. 1996).

Modifications in digestive enzyme activity have been found in several penaeid shrimp and related to the amount and quality of food (Lemos & Rodriguez 1998, Le Moullac et al. 1996, Le-Vay et al. 1993, Rodriguez et al. 1994). Rosas et al. (1995) found that the type and concentration of food influenced the ingestion rate of larval *L. setiferus*, which, in turn, affected metabolic rate. Changes in digestive enzyme activity were found under starvation conditions in juveniles of *Marsupenaeus japonicus* (Cuzon et al. 1980) and *Metapenaeus ensis* (Leung et al. 1990). Both studies found a decrease in digestive enzyme activity compared with fed shrimp.

Nitrogen excretion and metabolic rates are influenced by many factors, such as molt stage, feeding conditions, and level of activity. In this sense, O:N ratio has widely been used as an index of used substrate for oxidative metabolism (Chu and Ovsianico-Koulikowsky 1994, Dall & Smith 1986, Regnault 1981, Rosas et al. 1995). The catabolism of pure protein produced theoretical

*Corresponding author. E-mail: lcomoglio@hotmail.com

values of O:N of between 3 to 16 whereas the catabolism of equal quantities of proteins and lipids yield O:N values of between 50 and 60. Greater values of O:N correspond to an increase in lipid and carbohydrate catabolism (Mayzaud & Conover 1988).

The aim of this study was to evaluate the effect of starvation on digestive enzyme activity, oxygen consumption, ammonia excretion, and O:N ratio in *L. vannamei* juveniles. Afterwards, the effect of refeeding of starved juveniles was analyzed to assess the capability of shrimp to recover after prolonged starvation.

This information may contribute to a better understanding of the physiology of this commercially important shrimp species and will have an application in assisting with management in farms.

MATERIALS AND METHODS

Experimental Conditions and Design

Juveniles of *L. vannamei* were provided by a commercial farm, located in Mazatlán, Sinaloa, Mexico, during March 2001. The organisms were transported to the laboratory culture system of the Centro de Investigación en Alimentación y Desarrollo (CIAD) and fed with a commercial food during the acclimatizing period in 1000-L tanks. They were then transported to the laboratory, and groups of 20 organisms (wet weight = 0.998 ± 0.213 g) were maintained for different starvation periods (0, control group; 3, 6, 9, 12, and 15 days) in 10-L glass aquaria. Experimental conditions were 34 g · kg⁻¹ salinity, 24 °C water temperature, and 12D:12L. Water was completely renewed daily, and molts and dead organisms were removed. The natural seawater used in this study was pumped from a nearby beach (Cerritos beach), filtered through a cartridge filter of 5 µm and ultraviolet (UV) (Aquaplus, Mexico), and kept with aeration in a 600-L dark tank until use. Samples for bacterial load were regularly taken to confirm the absence of total heterotrophs and potential vibrios in the water.

Oxygen Consumption, Ammonia Excretion, and Atomic Ratio (O:N)

After each starvation period, groups of five individuals were placed in individual 500-mL respirometer chambers in a flow-through system using a continuous pump flow (ISMATEC, 12 mL/min flow). All measurements were done at the same time of day to obtain comparable data and assuming that all experimental shrimp were in minimum locomotive activity. Organisms were acclimated for 2 h in the beakers, and a sample of water from each chamber was taken to determine the initial concentration of oxygen and ammonia; flasks were sealed for 30 min, after which new samples were taken to measure final concentrations. The flow-through and the sealed periods were adjusted to avoid a depletion of oxygen concentration by more than 0.5 mg/L. Samples for ammonia excretion were filtered and fixed with H₂SO₄ (pH 2) and then frozen until processing.

The concentration of oxygen was measured using a polarographic oxygen electrode (YSI 59), and ammonia was determined by the indophenol technique (Parsons et al. 1984). Consumed oxygen and excreted ammonia were taken as being the net difference between the start and end of the sealed period. One out of every six chambers was left without a shrimp and measured as a control. The atomic O:N ratio was estimated according Taboada et al. (1998) using the individual values of oxygen consumption and ammonia excretion transformed to µg At · g⁻¹ · h⁻¹ as follows: oxygen values were multiplied by 62.5 (1000 to convert the milligrams into micrograms divided by the atomic weight of oxygen, 16),

ammonia values were multiplied by 58.9 [obtained through dividing 1000 by the product of the atomic weight of nitrogen (14) and the fraction of nitrogen in NH₃ (0.824)].

Digestive Enzyme Activities

After physiologic measurements, shrimps were dissected and the hepatopancreas stored at -70 °C in individual 1.5-mL microtubes until enzyme assays were done.

Frozen samples were homogenized in 1 mL ice-cold pure water. Homogenates were centrifuged (at 14,000 × g for 6 min at 4°C) and the aqueous supernatant, crude or diluted (1:10 v/v), was immediately used for enzyme analysis. The soluble-protein content was measured by the method of Bradford (1976), using a microplate reader at 495 nm. Duplicate assays for each sample were made. Trypsin activity was measured by the method of Erlanger et al. (1961) with N-α-benzoyl-DL-Arg-p-nitroanilide (BAPNA) as substrate. Chymotrypsin activity was assayed by the method of Delmer et al. (1979) using N-α-succinyl-L-alanyl-L-prolyl-L-phenyl-alanine-4-nitroanilide (SAPNA) as substrate. Hydrolysis for both enzyme activities was made in 0.1 M Tris-buffer, pH 8 at 25 °C, and the absorbance was measured at 405 nm. One unit of enzyme activity was defined as 1 µmol of p-nitroanilide liberated in 1 min at 25 °C.

α-amylase activity was assayed according to Bernfeld (1955) with 1.5% oyster glycogen as substrate in 10 mM phosphate buffer, pH 7. Absorbance measurements were made at 520 nm. For this method, one unit of enzymatic activity was defined as 1 mg of maltose liberated in 1 min at 37 °C.

General protease activity was estimated in homogenates using azocoll as substrate in phosphate buffer, pH 7.5 (Todd 1949). Absorbance was measured in a spectrophotometer at 520 nm. For this method, one unit was defined as the amount of enzyme that catalyzes the release of azo dye causing a $\Delta A/\Delta t = 0.001$ min (Walter 1988).

α-glycosidase activity was estimated using p-nitrophenyl-α-D-glycopyranoside as substrate in 50 mM phosphate buffer, pH 6. Absorbance was measured at 410 nm. One unit of enzymatic activity was defined as the amount of enzyme that hydrolyzes 1 µm of substrate per minute.

Post Starvation Refeeding Index

Other subgroups of organisms for each treatment (*n* = 6) were kept in individual chambers and exposed to a known amount of food previously lyophilized. The proximate composition of the food was 35% protein, 3.5% oil, 30% fiber, 16% ash, 12% humidity; average weight of each lyophilized pellet was 15.14 ± 2.28 mg; calorific content, 5.5 cal/mg of food. After 2 h 30 min, the nonconsumed food was removed and lyophilized again. The consumed food was calculated to measure the poststarvation refeeding index, defined as PSRFI (food consumed weight/body weight).

Bioenergetics Model

From a bioenergetic point of view, to integrate a model of energy partition for starved shrimp, we followed an equation (Bureau et al. 2000):

$$\text{DE requirement} = [\text{RE} + \text{Hem} + \text{HiE} + \text{HxE} \text{ [urine excretion energy (UE) + gill excretion energy (ZE)]} + \text{SE}]$$

This model originally included parameters where DE is digestible energy requirement, RE is energy gain, Hem is maintenance of energy requirement, HiE is heat increment of feeding, HxE is

nonfecal energy losses, and SE is surface loss or exuviae. With this model, a general energy balance model for starvation conditions in shrimp can be calculated.

However, in starved shrimps, the following parameters can be considered as 0:

$$DE = 0 \text{ (no feeding)}$$

$$HiE = 0 \text{ (no heat increment of feeding)}$$

$$SE = 0 \text{ (no exuvia)}$$

Hence, a model for starving shrimp could be

$$RE = -[Hem + HxE(UE + ZE)]$$

in which RE can be understood as endogenous energy needed to survive (Rosas, pers. comm.) and it is negative because in absence of energy input it is not possible to have energy gain *sensu stricto*. It is called also the scope for growth (SFG). Using this model, we calculated the endogenous energy (RE) for starving shrimp.

Statistical Analysis

To determine significant differences among starvation periods, one-way analysis of variance (ANOVA) and Tukey range test were used when the data were normal. Those results that were not normally distributed were evaluated through the Kruskal-Wallis test and Dunn's multiple comparisons (Daniels 1978). For both analyses, *P* was set at 0.05.

RESULTS

Weight and Survival

No significant differences were observed ($P > 0.05$) in relation to individual wet weight among treatments. However, survival decreased the longer the period of starvation (Table 1). The percentage of total molts were approximately 10% for 3- and 6-day treatments. No molting occurred after 6 days of starvation.

Oxygen Consumption, Ammonia Excretion, and O:N Ratio

Oxygen consumption increased significantly at 3, 6, and 9 days in starved animals (mean value $1.75 \text{ mg O}_2 \text{ h}^{-1} \cdot \text{g}^{-1}$) compared with the control. At 12 and 15 days, values were not significantly different from the control group (mean value $1.13 \text{ mg O}_2 \text{ h}^{-1} \cdot \text{g}^{-1}$) ($H = 14.1$; $P = 0.015$) (Fig. 1).

There were no significant differences in the amount of ammonia excreted between starved and control animals (mean value $0.08 \text{ mg N-NH}_3 \text{ h}^{-1} \cdot \text{g}^{-1}$, $H = 1.74$, $P = 0.88$) (Fig. 2). This may be because high standard deviations were observed, especially in the 6- and 12-day starvation groups (0.03 and $0.067 \text{ mg N-NH}_3 \text{ h}^{-1} \cdot \text{g}^{-1}$, respectively).

No significant differences between treatments were observed

Figure 1. Routine oxygen consumption of juveniles of *L. vannamei* after each starvation period (mean \pm SD). Treatments sharing the same letters are not significantly different ($P > 0.05$).

with regard to O:N atomic ratios ($H = 10.14$, $P = 0.071$) (Fig. 3). However, there was a trend toward increased ratios between days 3 and 9, suggesting that lipid was being catabolized. By day 12, the drop in the ratio to 10–20 suggests that protein was once again the main source of energetic fuel.

Enzyme Activity

Significant differences were found in the hepatosomatic index after different periods of starvation ($H = 25.6$, $P = 0.0001$). The index was significantly lower after animals were starved beyond 9 days. Beyond the ninth day, index decreased a further 50% until reaching the end of the experiment (Table 1). Hepatopancreatic total soluble protein was significantly affected by the period of starvation (ANOVA, $P < 0.05$). The highest value ($268.7 \pm 52.13 \text{ mg/mL}$) was obtained in the control, followed by the 3- and 6-day starvation experiments (mean value 159.8 mg/mL). The lowest significant values were found in the 9- to 15-day experiments (53.23 mg/mL) (Fig. 4).

Digestive enzyme activity was, in general, significantly affected by different periods of starvation. Hepatopancreatic digestive carbohydrases results are shown in Figure 5. Total amylase activity was significantly decreased by starvation (ANOVA, $P < 0.05$), from the highest value in fed juveniles (control) (0.016 ± 0.002 total U), followed by the 3- and 6-day experiments (mean value 0.011 total U) and the lowest value in the 9-, 12-, and 15-day starved groups (mean value 0.007 total U) (Fig. 5a). However, the specific activity increased as the soluble protein content decreased (Fig. 5b).

Glycosidase activity was significantly decreased (mean value 1.47 total U) by all starvation periods as compared with control fed animals (3.6 ± 1.5 total U) (Fig. 5c). For this enzyme, the specific activity also increased as the soluble protein content in the hepatopancreas decreased (Fig. 5d).

Proteinase activity was significantly affected by the starvation

TABLE 1.

Wet weight (g), survival (%), and hepatosomatic index (%) of the food-deprived shrimps *L. vannamei*.

	Starvation Days					
	0	3	6	9	12	15
Wet weight (g)	1.07 ± 0.1	0.86 ± 0.2	0.97 ± 0.23	0.99 ± 0.3	0.85 ± 0.1	1.04 ± 0.12
Survival (%)	100	90	90	65	65	55
Hepatosomatic index (%)	4.1 ± 0.7	3.3 ± 0.4	2.90 ± 0.45	2.5 ± 0.4	2.1 ± 0.3	1.98 ± 0.9

Data are mean \pm SD.

Figure 2. Routine nitrogen excretion of juveniles of *L. vannamei* after different starvation periods (mean \pm SD).

periods (ANOVA, $P < 0.05$) (Fig. 6). The highest value (5.3 ± 2.4 total U) was observed in the control, which was not significantly different from 3- and 6-day experiments, whereas the lowest value of total proteinase activity (1 ± 0.12 total U) was observed in the shrimps starved for 15 days (Fig. 6a). As with the carbohydrases, the specific activity of total proteinases was highest in shrimps starved for 12 days (Fig. 6b).

Total trypsin activity was significantly lower from the ninth day to the end of starvation (mean value 0.63 total U). Fed shrimp and those deprived for 3 and 6 days yielded a mean trypsin activity value of 2.58 total U (Fig. 6c).

Total chymotrypsin activity decreased over the period of starvation. Significant differences were found among the fed shrimps (45.41 ± 11.89 total U), the 3- and 6-day starvation groups (mean value 25.02 total U), and the 9-, 12-, and 15-day starvation groups (mean value 7.87 total U) (Fig. 6e). The specific activities of these latter two endoproteinases were not significantly affected by starvation (Figs. 6d and 6f).

Poststarvation Refeeding Index

The PSRFI was not significantly different between the control and 3- and 6-day starvation experiments (PSRFI = 5.09%, 4.71%, and 4.75%, respectively) whereas the amount of food consumed decreased for the 9-, 12-, and 15-day starvation experiments (PSRFI = 3.72%, 3.3%, and 2.97%, respectively) (Fig. 7) (Kruskal-Wallis, $H = 21.5$; $P = 0.006$).

Bioenergetics Model

Estimation of RE values indicates that at the beginning as well as at the end of the starvation period, shrimp needed the same endogenous energy to survive, whereas between 3 and 9 days they needed more energy, used essentially in respiration to maintain

Figure 3. O:N ratio of food-deprived juveniles of *L. vannamei*.

basal metabolism (Table 2). However, the routine respiration rate measured was 61% higher at day 3 of starvation than in fed shrimp and remained at this high level until day 9 of starvation. After then, values decreased to the same value as in controls.

DISCUSSION

In the current study the wet weight did not change with starvation, but survival rate decreased, and the suppression of molt after 6 days of starvation was observed. Anger and Spindler (1987) have observed in *Hyas araneus* a delay in molt under starved conditions and associated it with the point of reserve saturation (PRS). The PRS is the critical point where sufficient energy and/or essential substances have been accumulated to allow autonomous (food-independent) development through the entire rest of the molt cycle. Stuck et al. (1996) have also observed the inhibition of molting in response to starvation in *L. vannamei*. Under starvation conditions, a first event commonly observed is a weight loss in relation to energy expenditure for basal metabolism; after a few days, shrimp in premolt stages will not evolve further and refrain from exuviation, saving around 1.4 kJ (Read & Caulton 1980), which is the energy expenditure at molt. This means that shrimp have the adaptation to tolerate starvation, saving energy from exuvia, including the energy challenged to mobilize reserves, chitin digestion, and exuviation. In this way, shrimp could compensate for weight loss, maintaining body weight without significant changes, as was observed in the current study.

Litopenaeus vannamei juveniles, as many species of crustaceans, showed a biochemical adaptation response to an absence of food (decrease of digestive enzyme activities) using their own reserves (hepatopancreatic glycogen, protein, and probably lipids, estimated through O:N ratio variations) for homeostasis and to channel enough energy for basal metabolism in that period (Cuzon and Ceccaldi 1973, Dall and Smith 1986; Dall and Smith 1987, Leung et al. 1990).

Homeostasis in shrimp can change to help animals sustain severe food deprivation and survive; it is not instantaneous as the poststarvation and refeeding showed; and not all starved shrimps stayed alive (Table 1). It seems that under the experimental conditions tested, there was a kind of discrimination between shrimps that were capable of surviving starvation and those that were not. Some individuals may be more able than others to change some metabolic routes and resist food deprivation without significant morbidity. The previous life history of the animal before animals were sampled in the farm and used in experiments may also influence the variability between individuals to survive starvation. It

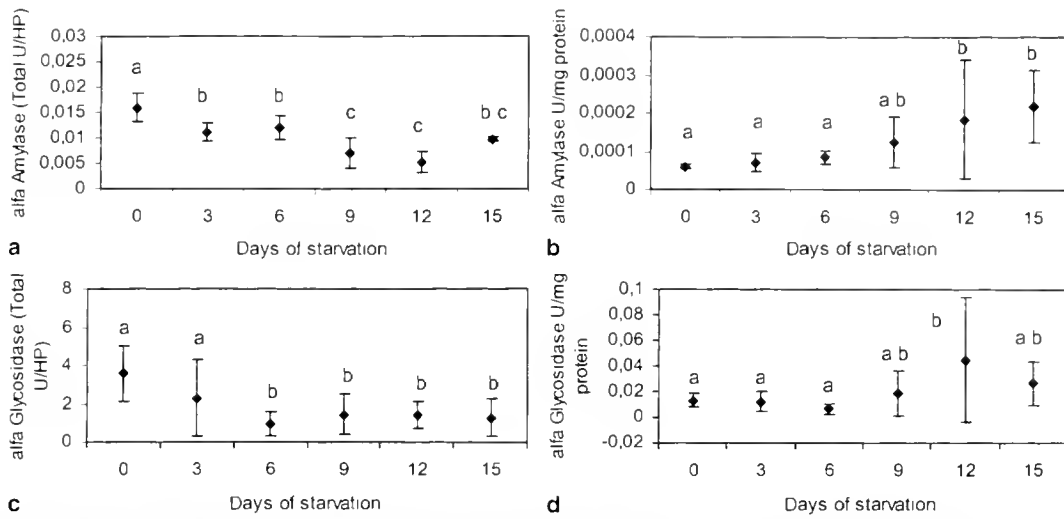

Figure 5. Total and specific activities of α -amylase (A and B) and α -glycosidase (C and D) of food-deprived juveniles of *L. vannamei* (mean \pm SD). Treatments sharing the same letters are not significantly different ($P > 0.05$).

must also be appreciated that these results will be biased due to the selection by farmers of the most robust and fastest growing individuals in the population.

According to these results, a high rate of mobilization of reserves was observed between days 3 and 9 of starvation, when the recovered energy (RE) was maximal. Shrimp reserves are mainly limited to lipids stored in the digestive gland. When shrimp are starving, they will use those reserves, increasing the energy debt and reducing the digestive gland weight and its components. Reduction of enzyme activity and soluble protein during starvation

underlined the change. It means the shrimp are biochemically and energetically well adapted to fasting because they could mobilize their reserves to be used as energetic sources; at the same time, the enzyme activity in the digestive gland was maintained. This type of strategy has been observed in other shrimp species. Cuzon et al. (1980) showed that *M. japonicus* used protein to obtain energy though the catabolism of amino acids present in digestive gland cells during a prolonged starvation period. A similar response was observed in *Penaeus esculentus* by Smith and Dall (1991), evidencing that shrimp can mobilize their own energetic reserves

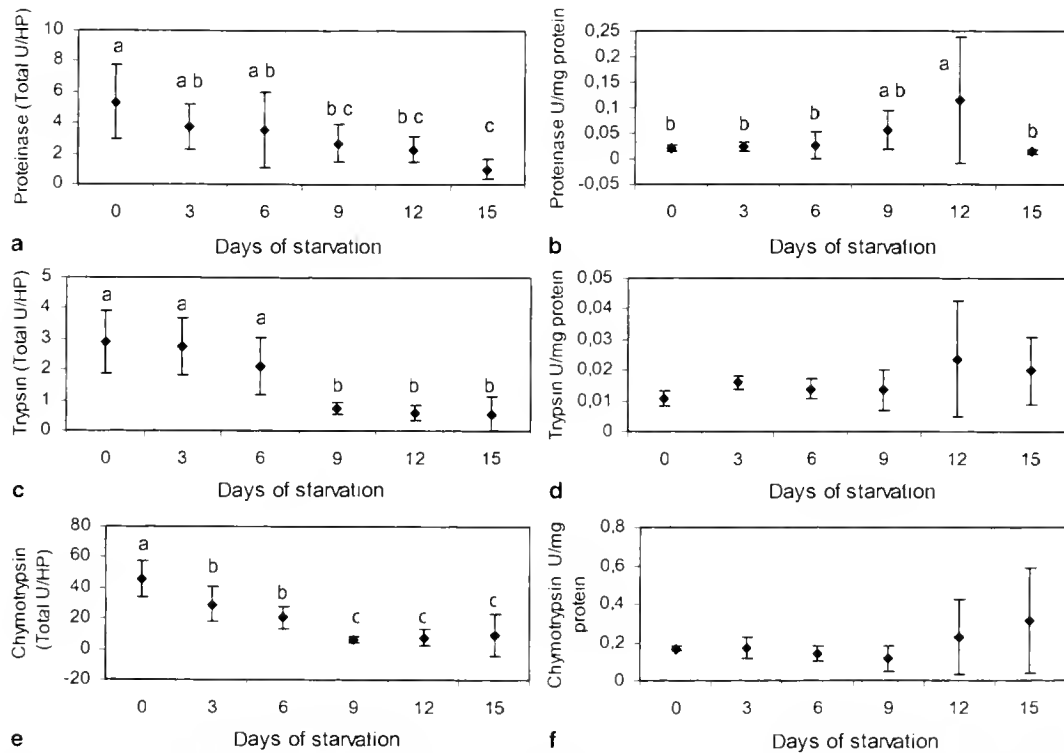

Figure 6. Total and specific digestive proteinases activities of juveniles of *L. vannamei* after different starvation periods (mean \pm SD). Treatments sharing the same letters are not significantly different ($P > 0.05$).

through catabolizing lipids (after 3 to 6 days of starvation) or protein to sustain themselves through food deprivation. Otherwise, a negative correlation was observed in starvation condition between total hepatopancreatic soluble protein and total activity for all measured digestive enzymes. This correlates well with the lower values of poststarvation refeeding rate.

In general terms, digestive enzymes follow the presence or absence of food. Samain et al. (1983) found that amylase increases in case of food deprivation with a peak, and then the enzyme production decreases as an adaptation to low nutrition status and to save energy. Digestive enzymes of *M. japonicus* showed a similar trend that supports previous results (Cuzon et al. 1980). However, results obtained after refeeding indicate that the necessary time to recover the digestive gland integrity depends on the fasting period. These results show that although *L. vannamei* have an adaptation mechanism to tolerate fasting conditions, recovery cannot be achieved if starvation is long enough to produce physical damage in the digestive gland and loss of enzyme synthesis. A pattern of variation for digestive enzymes presented by *L. vannamei* during a shorter experimental period differed from the one of *M. japonicus*. At day 15, for example, specific enzymes activity increased as a sort of adaptation to absorb the minute amount of food, but as energy expenditure increased, the peak disappeared shortly. Both amylases and proteases exhibited the same trend.

Mayzaud and Conover (1988) described starvation condition regarding the use of energetic substrates estimated through O:N ratio. It can be assumed that acetyl CoA, which is the final product of β -oxidation of fatty acids, could be challenged into biologic

TABLE 2.

O:N	70–100		50–60		2–16
Substrate	Glycogen		Triglycerides		Amino acids

* Charmantier (pers. comm.).

oxidation, requiring 46–52 oxygen atoms whereas, in normal condition, β -oxidation of neutral lipids requires 14–16 oxygen atoms to produce acetyl CoA. Increase in O₂ consumption of shrimps between days 3 and 9 of starvation with no increase of nitrogen excretion resulted in a high O:N ratio. Then, β -oxidation of hepatopancreatic lipid reserves could be occurring in this period. An explanation for a change can be found in the O:N ratio in which the use of lipid as energetic substrate was clear followed by protein as the main energy source. Ammonia excretion values provided indication on substrate oxidation; although nitrogen excretion was not significantly different from the control along the starvation period, O:N ratio values showed a trend to use lipids as energetic substrate between days 3 and 9 of starvation. Such a trend has also been evidenced in *M. rosenbergii* (Clifford & Brick 1983). After 12 starvation days, shrimp returned to the use of protein to derive energy. Likewise, as Mayzaud and Conover (1988) reported for planktonic crustaceans, a decrease in O:N ratio with time of starvation seemed to be common to all species with a predominantly protein-based metabolism. O:N ratio variation can be related to glucose homeostasis, through the regulation of glyconeogenesis (Cuzon et al. 2001) and glycolysis (Hochachka et al. 1988). These results are not in contradiction to those reported by Dall and Smith (1986) for *Penaeus esculentus*. These authors pointed out a reduction in metabolic rate with starvation providing a mechanism for prolonged survival. O:N ratios gave an explanation for successive fuel substrates as starvation increased in intensity (Table 3). Glycogen in the hepatopancreas is affected first, as in *Crangon crangon* (Regnault 1972), then neutral lipids are hydrolyzed, and toward the end of the starvation period, protein is used similarly as in *M. japonicus* juveniles (Cuzon et al. 1980).

This study has shown that *L. vannamei* is unable to sustain food deprivation for periods longer than 15 days. By comparison, the temperate species *M. japonicus* can survive 4 weeks of starvation. Both species show similar levels of digestive enzyme activity. However, basal metabolic rates in the former are higher because of its tropical habitat (24–27°C) as opposed to the temperate conditions (20°C) inhabited by the latter. They possess a similar level of digestive enzyme activities; then, there are good reasons, according to values of metabolism rates obtained in this study, to think that tropical species present a higher basal metabolism and activity that leaves them more dependent on regular food supply for their development.

The current work indicates *L. vannamei* is dependent on a regular food supply for its development, which has implications for its management in farms.

EFFECT OF DIETARY ASCORBIC ACID LEVELS ON REPRODUCTIVE PERFORMANCE OF SHRIMP, *LITOPENAEUS VANNAMEI* (BOONE), BROODSTOCK

SHAOBO DU, CHAOQUN HU AND QI SHEN

Laboratory of Applied Marine Biology, South China Sea Institute of Oceanology, The Chinese Academy of Sciences, 510301, Guangzhou, People's Republic of China

ABSTRACT This study was conducted to investigate the effect of dietary ascorbic acid (AA) on reproductive performance of shrimp *Litopenaeus vannamei*. Stay C-35 (a stable derivative, mainly monophosphate) was selected as AA source. Four grade levels of ascorbic acid equivalent (AAE) (0, 400, 800, and 1200 mg kg⁻¹ diet) were supplemented to the basal diet. Gonadosomatic index (GSI), hepatosomatic index (HSI), fecundity, and egg diameter were not significantly affected by supplemented AA levels ($P > 0.05$), although AA concentrations in hepatopancreas, ovaries, and eggs increased significantly with dietary AA levels ($P < 0.05$). Average daily spawns per female, hatching rate, and fertilization rate were also significantly affected by dietary AA levels ($P < 0.05$). Results of this study confirmed the importance of supplementation of AA to the basal diet and suggested that at least 800 mg AAE kg⁻¹ diet was needed to supplement to the basal diet to acquire excellent ovarian maturation and reproductive performance.

KEY WORDS: ascorbic acid, broodstock, *Litopenaeus vannamei*, reproductive performance

INTRODUCTION

Although nutrition has been identified as a key factor in the reproduction of broodstock shrimp, information on broodstock nutrition is still limited (Harrison 1990, Wouters et al. 2001b). Studies into the effect of nutrients on reproduction are essential to formulate high-quality broodstock diets as well as to elevate reproductive performance and quality of hatched nauplii.

Dietary ascorbic acid (AA) is an essential nutrient for penaeid shrimp (He & Lawrence 1993). Available studies into the role of this vitamin have focused on its effect in immature stages and suggested a dietary source of AA is required to prevent deficiency symptoms, such as reduced growth, melanized lesions underneath the exoskeleton, poor wound repair, and high mortality (Hunter et al. 1979, He & Lawrence 1993, Magarelli et al. 1978, Shiao & Hsu 1994). The importance of AA in reproduction has also been reported in fish and shrimp. In addition to the role of AA as an antioxidant and an enzyme cofactor in the formation of collagen (Barnes & Kodicek 1972, Hunter et al. 1979), which may be especially important during embryonic and larval development, it is also involved in the regulation of biosynthesis of steroid hormones (Hilton et al. 1979, Levine & Morita 1985, Seymour 1981). The essentiality of AA for fish broodstock was well established (Lavens et al. 1999a, Mangor-Jensen & Holm 1994, Sandnes et al. 1984, Soliman et al. 1986, Waagbo et al. 1989), and the importance of AA in shrimp reproduction has also been confirmed. Alava et al. (1993a, 1993b) reported AA-deficient diet retarded gonadal maturation of *Marsupenaeus japonicus*. Cahu et al. (1995) found AA levels in *Farfantepenaeus indicus* eggs were affected by dietary vitamin levels, and high hatching rate of *F. indicus* eggs were related to high AA levels in the eggs. Wouters et al. (2001a) detected a sharp decrease of AA content in spent ovaries and nauplii of *Litopenaeus vannamei* and suggested that AA was consumed during egg development and hatching.

Till now, there is still no information on the effect of dietary AA on ovary maturation and reproduction of *L. vannamei*. In a previous study, we successively substituted a natural diet consisting of 50% bloodworm (*Glycera chirori*) and 50% oyster (*Crassostrea rivularis*) with an artificial diet for broodstock *L. vannamei*. In the current study, we used this artificial diet as the basal diet and selected Stay C-35, a stable derivative, as AA source to investigate the effect of dietary AA on the reproductive perfor-

mance of *L. vannamei*. The effect of dietary AA levels on AA concentrations in ovaries, hepatopancreas, and eggs was also detected.

MATERIALS AND METHODS

Animals and Treatments

Domestic *L. vannamei* breeders were obtained from Dongfang Co. (Zhanjiang, China). They were kept in maturation tanks for 3 wk to acclimate experimental conditions and were fed the basal diet without any AA supplemented (Diet C1). A unisex system was used as described by Browdy et al. (1996): 4 tanks were stocked with 15 females each and 4 tanks with 15 males each. They were divided into four groups: Group C1–C4, which were subjected to Diet C1–C4, respectively. Each group consisted of a male tank and a female tank. After acclimation, female shrimps were unilaterally eyestalk-ablated with a pair of burned tweezers. To identify each female in the same group, part of its telson was cut, except five females were left intact and later sampled to test gonadosomatic index (GSI) and hepatosomatic index (HSI). The postablation phase of the experiment lasted for 50 days.

The maturation tanks were rectangular-shaped cement tanks (2 × 3 m², 55 cm water depth) in which sand-filtered and UV-treated seawater was exchanged at a rate of 200% daily. The physicochemical parameters of the water were average temperature, 28.5 °C; average salinity, 30 mg L⁻¹; photoperiod, 12 h light/12 h dark; and light intensity, 20 mW m⁻². Under these conditions, oxygen remained close to saturation, 6.2 g m⁻³, pH was 8.2 ± 0.1, while ammonia, nitrite, and nitrate levels remained almost the same as in the inlet water.

Diets and Feeding

In a previous study, the effect of 100% fresh food replacement with an artificial diet on ovarian maturation and spawning performance of broodstock *L. vannamei* was tested. Results showed that 100% artificial diet gave superior spawning performance to the fresh food control (consisting of 50% *G. chirori* and 50% *C. rivularis*), such as higher total spawn numbers (32 vs. 24), maturation ratio (90% vs. 70%), and daily spawns per female (0.091 vs. 0.069). As such, a fresh food replacement level of 100% was selected for the current study, and the same basal diet—with the

following composition related to dry matter: protein 48.98%, lipid 11.57%, and ash 15.42%—was used in the experiment. Ingredients and composition of basal diet are shown in Table 1. Four grade levels of ascorbic acid equivalent (AAE) were added to the basal diet (Table 2). ROVIMIX STAY C-35 (mainly monophosphate, containing 350 g L-AA kg⁻¹) was selected as the AA source for its excellent stability and bioavailability (Alexis et al. 1999). The diets were prepared in the following manner. All dried ingredients were smashed and sieved, mixed with 35% (w/w) water, and the resulting dough was pelleted with a meat grinder and dried at room temperature. Then the dried "spaghetti-like" 3-mm-diameter strands were crumbled to about 5-mm long and kept in sealed plastic bags at -20°C until use. Shrimps were fed 4 times daily (0800, 1100, 1400, and 1800 local time) with a measured ratio of 6% of the tank biomass (wet weight). Uneaten food was collected daily.

Broodstock Maturation and Spawning

After unilateral ablation, the females were visually examined for ovarian maturation stages at time 2000 every night according to Wouters et al. (2001a). For the females with intact telsons, when the ovary of the first female developed to stage VI, they were weighed and dissected, while keeping them on ice, to determine the gonadosomatic index (GSI = 100 × gonad weight/total body weight) and hepatosomatic index (HSI = 100 × hepatopancreas weight/total body weight).

The remained females ready to spawn were transferred to the corresponding male tanks to mate. Mature females with an attached spermatophore were placed in individual 120-L spawning tanks and after spawning were returned to their own maturation tanks. Fecundity (number of eggs per spawn) was estimated by

* ROVIMIX Stay C-35 (Roche Sunve Vitamins Ltd., Shanghai), mainly monophosphate, containing 350 mg L-ascorbic acid g⁻¹.

stirring the spawning tanks and counting three subsamples of 50-mL each. Fertilization rate was assessed in three 50-mL samples of each spawn, based on the presence of a double membrane in the eggs. A sample of 10,000 eggs was incubated at 29°C for estimating the hatching rate (% nauplii/fertilized eggs). All spawns were hatched individually. Hatching rate was calculated by counting the number of nauplii per spawn after positive phototropism selection. Egg diameter was estimated with a light microscope and a micrometer. About 80 mg eggs were sieved from each spawn and immediately rinsed in freshwater and stored at -70°C. Egg samples from the same group were pooled to obtain sufficient eggs for AA analysis. At the end of the experiment, five females with ovaries of stage II from each group were dissected. Hepatopancreas and ovaries were pooled and stored at -70°C for latter AA analysis.

Biochemical Analysis

Triplicate biochemical analysis of the basal diet was conducted according to the following standard procedures (AOAC 1990). Moisture was determined by oven drying to constant weight at 105°C. Crude protein (N × 6.25) was derived from Kjeldahl nitrogen analysis. Ash was determined at the residue after muffle furnace ignition at 550°C for 6 h. Total lipid content was determined by Soxhlet extraction with petroleum ether at 60°C for 8 h.

Tissue AA determinations were conducted by HPLC (HP1100) according to Alava et al. (1993b) and modified slightly. The analytical condition of HPLC was as follows: detection at UV-240 nm; column temperature, 30°C; eluent, 0.1 M KH₂PO₄ + 0.5% metaphosphoric acid w/v, pH 3.4; flow speed, 0.8 mL/min. AA was extracted from samples by the method of Nelis et al. (1997). Freeze-dried samples of 0.5 g were suspended in the extractant of 1% acetic acid-0.1% metaphosphoric acid-1 mM EDTA and ultrasonically homogenized for 10 min in an ice bath. The mixture was centrifuged for 5 min at 12,000g and passed through a 0.45-μm cellulose acetate membrane filter (SIGMA). Ten microliters of filtrate was introduced in the HPLC injection port. AA (Biochemika ultra, SIGMA) was used as standard.

Statistical Analyses

Each female in the same group was considered as an experimental unit for replication. Data of GSI, HSI, fecundity, daily spawns per female, egg diameter, fertilization rate, and hatching rate from each group were subjected to one-way ANOVA and subsequent Duncan's multiple-range test to determine difference in means. Prior to analysis, Levene's test for homogeneity of variances was used to verify the assumptions for further analysis.

There was no need to transform data. A regression analysis was used to determine the relationship between fecundity, egg diameter, fertilization rate, and hatching rate and spawn order. No correlations were detected between them, and spawn order was not considered as an additional factor to evaluate. An alpha level for all tests was set at 0.05. Statistical analysis was performed using Systat package (SYSTAT, 1996).

RESULTS

Average initial weight of female and male shrimps was 49.44 ± 4.29 g and 48.04 ± 4.81 g, respectively. As slightly mortality, probably induced by manipulation, occurred in some groups after 30 days, number of spawns was calculated per female per day.

Reproductive performance of different groups is shown in Table 3. Results showed that GSI increased with the increasing levels of AA, but the difference was not significant ($P > 0.05$). HSI values of female shrimps were also not significantly affected by dietary AA levels, though the HSI values of groups C2, C3, and C4 were slightly higher than that of group C1. Average daily spawns per female increased significantly with the AA levels ($P < 0.05$), and females of group C3 had the highest daily spawns, which was significantly higher than that of group C1 (0.074 vs. 0.050). Fecundity of all the females was similar, and there was no significant difference between the groups ($P > 0.05$). Similarly, egg diameter was almost the same and seemed not to be affected by dietary AA levels. Supplementation of AA to the basal diet increased the fertilization rate and hatching rate significantly ($P < 0.05$). Fertilization rate of group C2 (62.58%) was significantly higher than that of group C1 (53.76%) whereas group C3 had the highest fertilization rate (71.70%), which was significantly higher than those of groups C2 and C1. Hatching rate of group C4 was highest (61.08%), but was not significantly different with group C3 (58.13%), and the hatching rate of groups C1 (37.88%) and C2 (47.58%) was significantly lower than those of groups C3 and C4.

AA content in hepatopancreas, ovaries, and eggs of female *L. vannamei* is shown in Table 4. These females were at maturity stage II, with mean GSI values of 1.54 ± 0.05 for group C1, 1.57 ± 0.05 for group C2, 1.63 ± 0.09 for group C3, and 1.60 ± 0.06 for group C4, respectively. Results showed that there were much higher concentrations of AA in ovaries than in eggs and hepatopancreas. Tissue AA content was significantly affected by dietary AA levels. There were 19.34 mg kg^{-1} and 21.36 mg kg^{-1} in the hepatopancreas of groups C1 and C2, which were signifi-

cantly lower than those of groups C3 (37.13 mg kg^{-1}) and C4 (40.79 mg kg^{-1}). AA concentrations in ovaries and eggs increased significantly with the increasing AA levels ($P < 0.05$), and there was significant difference between the different groups.

DISCUSSION

The current study showed the importance of supplemental AA in broodstock diets of *L. vannamei* for enhanced ovarian maturation and reproduction. It appeared that AA concentration in the basal diet was sufficient to maintain normal survival, successive maturation, and spawns; however, for significantly higher daily spawns, fertilization rate, and hatching rate, supplementation of this vitamin to broodstock diet was necessary.

GSI and HSI indicated the effect of AA levels on the development of ovaries and hepatopancreas of female *L. vannamei*. GSI and HSI values of females fed the diet without AA supplementation were lower than those fed AA-supplemented diets, although the difference was not significant ($P > 0.05$). The period between eyestalk ablation and the first maturation of the females with intact telsons was only 5 days, and the relatively short period of time might account for the similar values of GSI and HSI. Females fed diets supplemented with 800 and 1200 mg kg^{-1} AA gave significantly higher daily spawns than those fed nonsupplemented diet. This result indicated that supplementation of at least 800 mg kg^{-1} AA to the basal diet was able to significantly enhance the ovarian maturation of female *L. vannamei*. Alava et al. (1993a, 1993b) also concluded the positive effect of AA on ovarian maturation of *M. japonicus* and suggested at least 500 mg kg^{-1} AA in the broodstock diet was necessary for ovarian maturation.

In this study, AA concentrations in hepatopancreas, ovaries, and eggs were widely affected by dietary AA levels. AA content in ovaries and eggs increased significantly with the increasing dietary AA levels. The similar trend has been confirmed in the studies on *M. japonicus* conducted by Alava et al. (1993b) and that on *F. indicus* by Cahu et al. (1995). There were higher levels of AA in ovaries than in hepatopancreas, as was shown in *M. japonicus* (Alava et al. 1993b), *Palaemonetes pugio* (Coglianese & Neff 1981), and *Macrobrachium rosenbergii* (Cavalli et al. 2001). The ovaries sampled in the current study were from females at maturation stage II, so the high levels of AA in pre-mature ovaries might be related to an increased requirement in the eggs as suggested by Hilton et al. (1979). Sandnes et al. (1984) and Soliman et al. (1986) showed that broodstock dietary AA was transferred to

eggs where it was stored for use during embryogenesis and development of larvae until the first feed intake. The positive effect of AA in shrimp production might be associated with the general role as an antioxidant (Wouters et al. 1999) as well as its action in the hydroxylation of protein-bound proline and lysine, which provide stable triple helical collagen through the embryonic stages (Barnes & Kodicek 1972). Guary et al. (1975) postulated that ovarian AA could be consumed during steroidogenesis, and the study of Calvalli et al. (2001) provided evidence for the possible demand for AA by the hydroxylating reactions in steroidogenesis in the ovarian follicle cells. Similarly, Wouters et al. (2001a) detected higher AA concentrations in immature, maturing, and mature ovaries than in ovaries of spent females and nauplii of *L. vannamei*, and suggested that the lost AA was used during egg development and hatching.

Results of the current study showed that supplementation of more than 800 mg kg⁻¹ AAE to the basal diet could significantly increase the fertilization rate and hatching rate of broodstock *L. vannamei*. Cahu et al. (1995) also suggested a positive relationship between improvement of egg hatchability and high AA concentration in broodstock diets as well as in eggs of *F. indicus*. The same positive effect of supplemented AA on egg quality and hatching rate was also observed in fish (Sandnes et al. 1984, Sofiman et al. 1986), and the feeding of an AA-deficient diet to broodstock fish could diminish reproductive performance (Hilton et al. 1979).

A dietary source of AA is required by all species of shrimp tested to date (Conklin 1997), though a possible limited synthesis

of AA was suggested in *P. californiensis* and *L. stylirostris* by Lightner et al. (1979). He & Lawrence (1993) indicated that dietary AA requirement of *L. vannamei* was size-dependent and decreased with increased size. They reported that minimum dietary AA levels required for normal survival were 120 mg kg⁻¹ and 41 mg kg⁻¹ diet for shrimp with an initial weight of 0.1 g and 0.5 g, respectively. Similarly, Lavens et al. (1999b) pointed out that for early postlarval *L. vannamei*, an optimal dietary AA level of 130 mg kg⁻¹ diet was needed to acquire best growth performance. However, for broodstock shrimp during ovarian maturation and reproduction, as the active synthesis of ovarian nutrients, egg yolk compounds, sex steroids, and embryo development will consume considerable amounts of AA, much higher levels of dietary AA should be required. This has been confirmed in the current study, which showed that supplementation of at least 800 mg kg⁻¹ AAE to the basal diet was needed to bring excellent ovarian maturation and reproductive performance.

ACKNOWLEDGMENTS

The authors would like to acknowledge Mr. Chen Wenlin for kindly offering shrimp breeders and experimental facilities. We also thank Yuehai Feed Co. Ltd and Mr. Zheng Shixuan for offering feed ingredients and manufacturing facilities. Sincere thanks are also given to Mr. Cheng Kaimin and Mr. Zhou Qicun for their help in feed manufacturing. This work was funded by the Science Innovative Project (No KSCX2-1-04-04) from the Chinese Academy of Sciences.

CHANGES IN THE BODY COMPOSITION OF ADULT MALE SOUTHERN ROCK LOBSTER, *JASUS EDWARDSII*, DURING STARVATION

L. E. MCLEOD, C. G. CARTER* AND D. J. JOHNSTON

School of Aquaculture, Tasmanian Aquaculture and Fisheries Institute, University of Tasmania, Locked Bag 1370, Launceston 7250, Tasmania, Australia

ABSTRACT This experiment determined the effect of starvation on the chemical composition and tissue histology of the abdominal muscle and digestive gland in adult male southern rock lobsters *Jasus edwardsii* during 14 and 28 days. Individual lobsters ($n = 6$) were stocked into 34-L tanks ($17.5 \pm 1.5^\circ\text{C}$) and either fed or starved over 14 and 28 days and also compared with lobsters ($n = 6$) killed for initial samples at the start of the experiment. Starved lobsters showed a significant reduction in crude lipid from the digestive gland at day 14 and from the abdominal muscle at day 28 when compared with the initial population. Histologic investigation of the digestive gland showed a lower density of lipid droplets in both day 14 and day 28 starved lobsters, with this depletion apparently causing structural damage to the digestive tubule in lobsters starved for 28 days. Histologic investigation of glycogen levels in digestive tubules showed a decline with starvation. Available energy was significantly affected by the crude lipid content of both organs although the digestive gland contained significantly higher absolute amounts. Starvation forces the use of body reserves to maintain metabolic functions; the order and quantity of depletion indicated the minimum requirements for survival and highlighted differences in the strategies used by crustaceans.

KEY WORDS: glycogen, histology, *Jasus edwardsii*, lipid, southern rock lobster, starvation

INTRODUCTION

The southern rock lobster *Jasus edwardsii* (Hutton, 1875) (Palaemonidae) is found along the coastlines of New Zealand and southern Australia and forms an important fishery in these regions (Thomas et al. 1998). Aquaculture is also under development in New Zealand and Australia; current strategies on-grow wild-caught puerulus, postpuerulus, and juveniles to market size (Jeffs & Hooker 2000, Thomas et al. 1998). Research into broodstock management and larval propagation is underway, and whereas there is a major focus on female broodstock and larval quality (Smith et al. 2003a, Smith et al. 2003b), little information is available on male rock lobsters.

Starved crustaceans, like all animals, must use body reserves to supply energy to maintain metabolism (Hervant et al. 1999, Lemmens 1994, Virtue et al. 1993), and the change in body composition indicates both the sequence and level of depletion of different body reserves. For decapod crustaceans there is conflict in the literature about the order and amount of reserve utilization and hence the role of protein, lipid, and carbohydrate during starvation. Many marine crustaceans metabolize lipid initially, using protein only after lipid reserves are depleted (Dawirs 1987, Regnault 1981). For example, rapid depletion of digestive gland lipid was documented in adult tiger prawns *Penaeus esculentus* (Barclay et al. 1983, Chandumpai et al. 1991), adult *Crangon crangon* (Regnault 1981), and in larval and adult shore crabs *Carcinus maenas* (Dawirs 1987, Heath & Barnes 1970). In contrast, larvae of the spider crab *Hyas araneus* (Anger & Dawirs 1982) and adult Antarctic krill *Euphausia superba* (Virtue et al. 1993) use body protein initially and lipids last. Therefore, assumptions about the use of body reserves as metabolic substrates by crustaceans during periods of nonfeeding or starvation should be avoided.

Lipid is used as the primary energy source to sustain onshore swimming activity of nonfeeding (starved) southern rock lobster puerulus prior to settlement (Jeffs et al. 1999, Jeffs et al. 2001, Lemmens 1994, Wells et al. 2001). Enzyme profiles also suggest

that lipid as well as carbohydrate are used by puerulus and that protein may be used for energy following depletion of these reserves (Johnston, 2003). Lipid is also a major source of energy in phyllosoma larvae with polar lipids and polyunsaturated fatty acids particularly important (Nelson et al. 2003). Energy utilization in broodstock is less understood, and only recently has the importance of broodstock diet been linked with phyllosoma quality and survival in hatcheries (Smith et al. 2003a). This study will be the first to examine utilization of energy reserves in male southern rock lobster broodstock through dedicated starvation experiments and will complete our understanding of energy utilization in the life-cycle of the southern rock lobster. The aims of this study were to measure and compare the standard growth parameters and chemical composition of the abdominal muscle and digestive gland in adult male southern rock lobsters (*J. edwardsii*) from an initial population and those that were fed or starved for 14 days and 28 days. Histology of the digestive gland has proved a sensitive indicator of nutritional condition (Johnston et al. 2003) and was used in the current study.

MATERIALS AND METHODS

Experimental Procedure

The experiment was conducted at the School of Aquaculture, University of Tasmania. Captive male southern rock lobsters (*J. edwardsii*) were obtained from Marine Research Laboratories (MRL), Hobart, Tasmania. This experiment was run during two time blocks with a total of 30 lobsters used. Each time block had an initial group, day 14 fed, day 14 starved, day 28 fed, and day 28 starved; each treatment consisted of 3 lobsters randomly allocated to individual experimental tanks. Prior to the commencement of each time block, lobsters were acclimatized to the system for 7 days. During acclimatization, any mortalities or molts were replaced with similar-sized animals from the stock population.

The system was maintained at $17.5 \pm 1.5^\circ\text{C}$ and kept dark to increase feeding time. Water exited the 12 experimental tanks via

*Corresponding author. E-mail: Chris.Carter@utas.edu.au

a standpipe and was returned to the biofilter with 3–5% replacement every 2 days. Water quality parameters (salinity, dissolved oxygen, ammonia, nitrate, and nitrite) were monitored to ensure water quality remained within limits recommended for spiny lobsters (Jeffs and Hooker 2000). At the start of each time block, an initial sample of three lobsters were placed on ice to induce a chill-coma and used for assessment of weight, carapace length, organ size, and chemical and histologic composition (see below). At the same time, weight and carapace length were measured in 12 lobsters that were then stocked individually into experimental tanks and randomly assigned into treatments (fed or starved over 14 or 28 days). Single animals were stocked to prevent effects of agonistic behavior and cannibalism (Thomas et al. 2003). Lobsters were fed mussel (*Mytilus edulis*) every 3 days at 1330, and uneaten food and waste was siphoned out the next morning. At the end of the experiment, lobsters were induced into a chill-coma and the carapace removed to reveal the digestive gland. Samples of digestive gland tissue were fixed immediately for histology. Digestive gland and abdominal muscle tissue was wrapped in foil and frozen at -40°C for freeze-drying and analysis of chemical composition (discussed in following section).

Chemical Analysis

Digestive glands and abdominal muscle were analyzed for chemical composition using standard methods to determine dry matter (freeze dry to constant weight); nitrogen (Kjeldahl using a selenium catalyst) (AOAC 1995); crude protein calculated using % nitrogen $\times 6.25$; crude lipid [Soxhlet apparatus and PET extraction (AOAC 1995)]; ash [muffle furnace at 550°C for 16 h (AOAC, 1995)]; and carbohydrate (nitrogen-free extract, NFE), determined by the difference between dry matter and sum of crude protein, lipid, and ash. Energy was calculated from the chemical composition using values of 23.6 kJ g^{-1} for protein, 38.6 kJ g^{-1} for lipid, and 17.2 kJ g^{-1} for carbohydrate (Jobling 1994).

Histology

Samples of digestive gland were dissected and fixed in 2.5% glutaraldehyde in 0.1 M phosphate buffer (pH 7.4) for 2 h at room temperature. Following washes in 0.1 M phosphate buffer (pH 7.4), samples were dehydrated in a graded series of ethanol and half the tissue post-fixed in 1% osmium tetroxide in 0.1 M phosphate buffer for 1 h. Tissue was washed in 0.1 M phosphate buffer.

embedded in glycolmethacrylate (JB4) resin, sectioned at $2 \mu\text{m}$, and then stained with polychrome blue. The other half of each tissue sample was processed routinely for wax histology, sectioned at $5 \mu\text{m}$, then stained for glycogen using the periodic acid-Schiff (PAS) technique (Bancroft and Cook 1994). A negative diastase control was used to obtain more specificity in detecting glycogen (Humason 1972), and a positive control of trout mucus was initially stained with samples.

Statistical Analysis

Mean values are reported \pm standard error (SE). Each lobster sampled was assessed as a single replicate. The chemical composition values for digestive gland and abdominal muscle were the mean of two duplicates. Data were pooled to give six replicates for each of the five treatments (day 0, day 14 fed, day 14 starved, day 28 fed, and day 28 starved). Normality and homogeneity of variance were confirmed (SPSS version 8). Comparison between means was by one-way analysis of variance (ANOVA) and post-hoc comparison using Tukey's HSD (SPSS version 8). Significance was accepted at probabilities of 0.05 or less.

RESULTS

Chemical Composition

There were no significant differences in carapace length between the initial group and the different treatments nor were there were any significant differences in whole body wet weight, abdominal muscle index (ABI), or digestive gland index (DGI) between fed and starved lobsters (Table 1). However, starved lobsters showed a general trend of lower mean whole body weight and significantly different changes in wet body weight (Table 1). Starved lobsters tended to show a lower DGI, but multiple comparison was not sensitive enough to show which treatments were significantly different (Table 1).

Only crude lipid and gross energy content of abdominal muscle tissue were significantly different between treatments (Table 2). After 28 days of starvation, the abdominal muscle of lobsters had lower mean crude lipid than the abdominal muscle of lobsters in the initial population; no other significant changes were shown statistically. The correlations between chemical composition parameters of the abdominal muscle in fed and starved adult lobsters were investigated. Dry matter was positively correlated with crude

TABLE 1.
Growth and condition indices (% wet weight) of *J. edwardsii* (mean \pm SE, n = 6), when fed or starved for 14 or 28 days.

¹ Carbohydrate was calculated by difference (Dry matter - (crude protein - crude lipid - ash)).

² Energy was calculated using values of 23.6 kJ.g⁻¹ for protein, 38.6 kJ.g⁻¹ for lipid and 17.2 kJ.g⁻¹ for carbohydrate (Jobling, 1994).

Values which share the same superscript are not significantly different.

♣ Multiple comparisons were not sensitive enough to identify significantly difference mean values.

protein ($r = 0.50$, $P \leq 0.01$), and energy content ($r = 0.69$, $P \leq 0.01$), and energy content was positively correlated with crude protein ($r = 0.55$, $P \leq 0.01$) and crude lipid ($r = 0.37$, $P \leq 0.05$).

Crude lipid content of the digestive gland was significantly lower in day 14 starved lobsters than at day 0 (Table 2). There were no other significant differences between treatments although crude lipid in day 28 lobsters was suggestive of the same trend. Carbohydrate was significantly higher in day 14 starved lobsters compared with day 14 fed and the day 0 group. There were no significant differences in dry matter, crude protein, ash, or energy. Dry matter was not correlated with crude lipid ($r = 0.15$, $P > 0.05$) or carbohydrate ($r = 0.16$, $P > 0.05$), and crude lipid was not correlated with digestive gland energy content ($r = 0.15$, $P > 0.05$). There was a significant negative correlation between crude lipid and carbohydrate ($r = -0.43$, $P \leq 0.05$).

Histologic Examination of the Digestive Gland

Lipid droplets in epithelial cells of the digestive gland tubules from the initial lobster population were densely arranged in the apical cytoplasm and less dense adjacent to the basal lamina (Fig. 1A). The epithelia of tubules from lobsters fed for 14 days had densely arranged lipid droplets that were spaced throughout the cytoplasm (Fig. 1B). Epithelial cells in lobsters starved for 14 days had a large number of empty vacuoles concentrated apically with densely arranged lipid droplets in the cytoplasm adjacent to the basal lamina (Fig. 1C). This agrees with the reduction in crude lipid found in the chemical composition data. Lobsters fed for 28 days had tubules with densely arranged lipid droplets, similar to the 14-day fed lobsters. Epithelial cells of lobsters starved for 28 days had large amounts of empty vacuoles apically around the tubule lumen, with both loosely arranged lipid droplets and empty vacuoles adjacent to the basal lamina and outer membranes ruptured (Fig. 1E).

The digestive gland epithelial cells in the initial lobster population had minimal glycogen granular material (Fig. 2A). The

negative control, diastase treatment was used over all treatments and all had less intense staining, indicating stained material was glycogen (Figs. 2B, 3D, 4B, and 4D). Epithelial cells from lobsters fed for 14 days had intense positive staining for glycogen (Fig. 3A) whereas starved lobsters had fewer positive staining granular bodies (Fig. 3C). Cells from lobsters fed for 28 days had less glycogen (Fig. 4A) than 14-day fed lobsters, although cells from lobsters starved 28 days had a much lower quantity of glycogen than 14 day starved lobsters (Fig. 4C).

DISCUSSION

Chemical Composition

The nonsignificant trend of lower whole body weight in starved lobsters is consistent with body tissue being used during food deprivation to maintain metabolism (Hervant et al. 1999, Lemmens 1994, Virtue et al. 1993). However, unlike vertebrates, crustacean body volume is set by their rigid exoskeleton (Stuck et al. 1996), therefore to maintain this set volume any change in body mass is counteracted by a change in water content (Barclay et al. 1983, Hervant et al. 1999, Stuck et al. 1996). The mass of digestive gland and abdominal muscle as a percentage of whole body weight showed opposite changes with starvation, which support conclusions that organs respond differently to nutritional stress (Schirf et al. 1987).

The total wet weight and percent dry matter of abdominal muscle showed no obvious or significant trends when lobsters were starved. However, the reduction in percent dry matter of abdominal muscle in lobsters fed for 28 days indicates possible catabolism of muscle tissue. This, in addition to the increases in uneaten feed recovered from tanks of day 28 fed lobsters, indicated they had entered premolt shortly after day 14 and were close to ecdysis at time of sampling (day 28). Crustaceans stop feeding during early premolt and use body reserves until the shell hardens

Figure 1. Transverse sections (TS) of a digestive gland tubule from *J. edwardsii*. Tissue fixed in osmium for detection of lipid. (A) Initial population. (B) Day 14 fed lobster. (C) Day 14 starved lobster. (D) Day 28 fed lobster. (E) Day 28 starved lobster. Scale bar, 50 μ m. (Hs, hemolymph space; Lu, tubule lumen; Ld, lipid droplets; Lv, empty lipid vacuole; B, B-cell vacuole.)

(Barclay et al. 1983, Chang & O'Connor 1983, Factor 1995, Harrison 1997, Hiller-Adams & Childress 1983, Jones et al. 1997).

Although abdominal muscle crude protein showed a small range (22.0–23.7% wet weight) between treatments, it was positively correlated with the percent dry matter ($P \leq 0.01$); a similar correlation was also found in Pacific white shrimp *Penaeus vannamei* (Stuck et al. 1996). Starved lobsters tended to have a lower

abdominal muscle percent crude protein than lobsters fed over the same time period, a trend also found in adult tiger prawns when starved for 14 days (Barclay et al. 1983) and in small adult *J. edwardsii* lobsters (80–90 mm carapace length) fed once every 10 days (Musgrove 1997). Lobsters fed for 28 days showed lower percent crude protein than lobsters from day 0 and day 14 fed, and this reduction is explained by muscle protein decreasing to permit

the escape of lobster from the old exoskeleton during the molt cycle (Chang & O'Connor, 1983). The significantly lower lipid level in the abdominal muscle of starved lobsters at 28 days compared with the initial population is consistent with findings in starved adult tiger prawns (Chandumpai et al. 1991). The significant correlation between percent crude lipid and abdominal muscle energy content indicates that although the mean absolute wet weight of crude lipid stored in the abdominal muscle was less than 0.4% whole body wet weight), changes still affected the energy matrix within the abdominal muscle during starvation, which somewhat conflicts with suggestions that the low levels of lipid in the lobster muscle are mostly structural and are not normally available for energy production (Dall 1981).

The trend of lower percent dry matter in the digestive gland of starved lobsters, indicating a reduction of total body stores, further supports the digestive gland being the primary organ for energy storage in decapod crustaceans (Dall 1981, Gibson & Barker 1979, Icely & Nott 1992). The percent crude protein of digestive gland increased in starved lobsters as has been found in the digestive gland of the marine carnivorous prawn *Pandalus platycero* (Whyte et al. 1986). However, the apparent increase in crude protein content is due to the reduction in digestive gland tissue mass rather

than an increase in the amount of protein. In general, decapod crustaceans have higher digestive gland lipid than most other groups (Gibson & Barker 1979). This study found large adults (117.42–119.34 mm carapace length) had a crude lipid content of 47–71% digestive gland dry weight and within the range for juvenile southern rock lobsters in some studies (Crear et al., 2001) but not others (Johnston et al. 2003, Ward et al. 2003). Generally, the digestive gland lipid content in the current study was considerably higher than in other decapod crustaceans (Barclay et al. 1983, Chandumpai et al. 1991). Digestive gland crude lipid also appears to vary within the lobster family: 40–50% for adult *J. lalandii* (carapace lengths 70–89 mm) (Cockcroft 1997); 17–65% for adult *Homarus americanus* during 102 days of starvation (Stewart et al. 1972); and <12% for adult *J. edwardsii* (Musgrove 1997). The absolute amount of crude lipid was higher in the digestive gland (6.41–12.96 g) than in the abdominal muscle (1.17–2.94 g), which further emphasizes the importance of the digestive gland as an energy store in crustaceans (Cockcroft 1997, Dall 1981, Jeffs et al. 2001).

The increase in the estimated carbohydrate levels of digestive gland in lobsters fed for 28 days may be explained by the increase in total glycogen deposited in digestive gland and epidermis during

the transition of spiny lobsters into premolt (Schwabe et al. 1952). Although later publications have challenged some of the conclusions from this paper (Dall 1981, Stewart et al. 1972), the increase in digestive gland glycogen was also found to be significantly higher in prawn *P. kerathurus* before molting (Hilmy et al. 1986). The negative correlation between carbohydrate and crude lipid in the digestive gland may be explained by the suggestion that carbohydrates act as an intermediate energy substrate following the breakdown of other storage products such as lipids (Jeffs et al. 1999) and may also explain increased content due to the breakdown of lipid. The method of carbohydrate quantification used was to calculate the difference between dry matter and the other measured tissue macro-chemical components and gave estimated ranges of 1.6–42.7 and 56.4–212.0 mg/g dry tissue for the abdominal muscle and digestive gland tissues, respectively. The carbohydrate content of the digestive glands from the day 14 and day 28 starved lobsters were 212 and 140 mg/g dry tissue, respectively, and appeared very high in comparison to other samples in the current study and to some other studies on crustaceans (Hilmy et al. 1986, Whyte et al. 1986). Digestive gland carbohydrate varied between 17 and 47 mg/g dry material, depending on dietary carbohydrate, in small (<10 g) *J. edwardsii* (Johnston et al. 2003). However, higher values have been reported in the digestive gland of lobsters including 168 mg/g dry tissue for adult (470 g) *Homarus americanus* (Floreto et al. 2000). The results from the current study indicate that further investigation of carbohydrate dynamics using direct measurements would be informative and also that the histologic approach used in the current study went some way to addressing this issue. The histologic assessment of glycogen is clearly more sensitive than estimating carbohydrate by difference (see below).

Histology

The prevalence of empty lipid vacuoles in digestive gland epithelial cells of unfed lobsters (Figs. 1C and E) confirms that lipid is used by *J. edwardsii* broodstock during periods of starvation and supports the reduction of lipid content in the digestive gland of starved lobsters as determined by chemical analysis. Tissue histology also shows that short-term depletion of lipid reserves has no effect on structure of the digestive gland tubules, which remain unchanged in lobsters starved for 14 days. But after 28 days of starvation, when lipid reserves are near exhausted, outer cell mem-

branes are degraded and the cytoplasm is diffuse. Such tissue damage was also observed during periods of nutritional deprivation in adult freshwater crayfish marron *Cherax tenuimanus* (Jussila 1997). Although change in the number and size of B-cells or R-cells is used as an indication of nutritional stress (Al-Mohanna and Nott 1987, Niles et al. 1993), no such differences were apparent between the treatments in this trial.

Glycogen was also depleted from digestive gland epithelia during starvation with greater depletion from tissues the longer lobsters were starved (Figs. 3C and 4C). Although it is widely accepted that digestive gland glycogen reserves are rapidly depleted over a period of nonfeeding in crustaceans (Dall 1986, Gibson & Barker 1979, Hilmy et al. 1986, Jeffs et al. 2001), this is one of the few studies to demonstrate this fact using tissue histology. The higher intensity staining in the day 14 fed lobsters indicates they are in better nutritional condition than lobsters from the initial population and agrees with chemical composition data. It is unclear why lobsters fed for 28 days had lower glycogen than lobsters fed for 14 days, as 28 days fed animals had higher levels of carbohydrate, as determined by difference. It is possible this discrepancy may be due to resorption of glycogen by day 28 lobsters for chitin synthesis as they were entering premolt during the latter stages of the experiment (Aiken 1980, Chang, 1995). This physiologic mechanism may not be apparent from the chemical composition data, which only estimated total carbohydrate.

CONCLUSIONS

This study has confirmed the importance of lipid and glycogen as energy sources for southern rock lobster broodstock using the combination of chemical analyses and tissue histology. Research on starvation effects in southern rock lobster over longer time periods may show more of the significant differences between fed and starved animals found in other crustaceans. There appears to be a relationship between crustacean body mass and the energy reserve composition, this may indicate a switch in dietary needs with carapace length. The increase in the weight of apparent carbohydrate in both the abdominal muscle and digestive gland during starvation is cause for investigation as these results conflict with the reduction of body reserves during starvation. The results from this study, together with further research into the effect of starvation on southern rock lobster biochemical composition, should aid in the development of understanding of the importance of individual energy reserves.

ABSTRACT Total lipid, lipid class, and fatty acid analyses were conducted on fed and starved stage I and II phyllosoma of the western rock lobster *Panulirus cygnus*. In both stages, the decrease in dry mass of starved larvae and increase in dry mass of *Artemia*-fed larvae were accompanied by a decrease and increase in lipid content, respectively. Lipid accounted for 6.7% of the decrease in dry mass in starved stage I larvae, which increased to 35.0% in stage II larvae. Also, lipid accounted for 6.2% of the increase in dry mass of fed stage I larvae, increasing to 19.2% in stage II larvae. The major lipid classes in all phyllosoma samples were polar lipids (84.1–94.3%) followed by sterols (6.6–12.1%; mainly cholesterol). Gravimetrically, fed larvae increased predominantly in polar lipid whereas in starved larvae, polar lipid was the major lipid class catabolized, with the sterol content not changing significantly. Hydrocarbons, wax esters, diacylglyceryl ether, triacylglycerols, and free fatty acids were all minor lipid classes (<5% of total lipid). Fatty acid analysis showed six major components present: 16:0, 18:1n-9, 18:0, 20:4n-6 (arachidonic acid; AA), 20:5n-3 (eicosapentaenoic acid; EPA) and 22:6n-3 (docosahexaenoic acid; DHA). These fatty acids all increased gravimetrically in fed larvae and decreased in starved larvae. In starved larvae, small decreases were seen in the relative contribution of EPA, DHA, 16:1n-7, and 18:1n-9, with AA increasing. In fed larvae, most of the major fatty acids remained at a similar relative level, and larvae were able to accumulate AA and EPA, but not DHA, above the relative level (%) in *Artemia*. The results are useful in the identification of nutrients required during development and as such with the design of diets used in phyllosoma culture.

KEY WORDS: *Artemia*, fatty acids, lipid, *Panulirus cygnus*, phyllosoma, polar lipid, rock lobster

INTRODUCTION

With increased product demand and value, aquaculture or enhancement of spiny lobster fisheries is currently receiving considerable interest due to wild fisheries being fully exploited worldwide (Kittaka 1994, Phillips et al. 2000). The western rock lobster, *Panulirus cygnus*, is found on the lower west coast of Australia and supports the world's largest rock lobster fishery (Phillips et al. 2000). To ensure sustainability, a major spiny lobster aquaculture industry would need to be based on culture of phyllosoma from hatching through their entire larval development (Crear et al. 1998, Kittaka and Booth 1994). A major hurdle in complete culture of spiny lobsters is the long and complex larval component of its life history. Although the larval life cycle has been completed in the laboratory for a number of species, only limited success has been achieved (e.g., Booth 1995, Kittaka 1997), with many studies experiencing high mortality in early stages (e.g., Kittaka et al. 1997, Kittaka 1988, Kittaka & Ikegami 1988).

Nutrition is regarded as a key factor controlling survival and growth in crustacean larval culture (Mikami et al. 1995). Very little is known about the feeding of phyllosoma in the wild, creating a need for larval nutritional research, as nutritional studies on spiny lobsters (Palinuridae), particularly on the larval stages that are difficult to rear, are scarce (Kanazawa and Koshio 1994, Phleger et al. 2001). Phyllosoma have been reared on *Artemia* and mussel gonad with varying success (Illingworth et al. 1997, Kittaka 1988), however, appropriate nutrition requires the identification of the essential elements within the diet (Kanazawa and Koshio 1994). Lipid has been found to be of prime importance in crustacean larval stages (Kattner et al. 1994, Sasaki et al. 1986), and appears to be the main storage product in late stage phyllosoma, which is then used as an energy source during the nonfeeding puerulus stage (Jeffs et al. 1999, Jeffs et al. 2001).

Starvation experiments are one means to determine nutritional requirements of fish and crustacean larvae, with the retention of specific fatty acids (FA) during starvation being interpreted as a requirement for that specific FA (Olsen 1998). Koven et al. (1989) found fish larvae (*Sparus aurata*) conserved essential *n*-3 FA during starvation, especially docosahexaenoic acid (DHA) and eicosapentaenoic acid (EPA), and considered this to be a reasonable biochemical strategy as these FA are more valuable as components of membranes than as energy sources. Biochemical studies during starvation and feeding of prawn larvae have also supplied valuable information on the best nutrient specification of food for the larvae (D'Souza 1998).

The objective of this work was to examine which lipids (lipid classes and fatty acids) were of greater nutritional importance for stage I and II *P. cygnus* phyllosoma by comparing patterns of conservation and loss in starved and fed larvae. The aim was to provide information that would be useful in defining suitable diets with profiles appropriate for phyllosoma culture.

MATERIALS AND METHODS

Broodstock

The study was undertaken at the Western Australian Marine Research Laboratories, Perth, Australia. Broodstock animals were kept in the laboratory under 12L:12D light cycle and fed daily with live mussels (*Mytilus edulis*) and routinely with fish and abalone. Larvae used in the stage I experiment hatched from a lobster (128.3 mm carapace length) mated in the laboratory, with oviposition of eggs (24 May 2001) at 25°C and incubation in a tank at 22°C (32–34 ppt), with larvae hatching after 39 days incubation. Larvae used in the stage II experiment hatched from a lobster (105.0 mm carapace length) mated in the laboratory, with ovipo-

sition of eggs (29 July 2001) at 25°C and incubation in a tank at 19°C (32–34 ppt), with larvae hatching after 57 days incubation.

Experimental System

The system used for rearing the phyllosoma has successfully been used to rear southern rock lobster (*Jasus edwardsii*) phyllosoma to their final stage (Ritar 2001). Seawater used in the experiments was heated to 23°C, filtered to 1 µm and UV sterilized (UViVF-9, 30 W) before entering the circular 30-L plastic rearing tubs. Water entered the tubs through four equally spaced nozzles (jets) positioned close to the bottom perimeter of the tub, with another two toward the bottom center of the tub to provide a circular water flow, thereby keeping phyllosoma moving in the water column. Each tub had a water flow of approximately 1 L/min, and the volume was maintained at 10 L. Excess water exited through screens positioned on the side of the tubs. Phyllosoma were fed daily with *Artemia* at 3/mL. Every morning, remaining *Artemia* were removed from the system by replacing the usual screens, "feeding filters" (200 µm), with "cleaning filters" (1500 µm) for approximately 1 h that allowed the *Artemia* to be flushed out of the tubs. The feeding filters were replaced and freshly enriched *Artemia* were then added to the tubs. Phyllosoma were transferred to clean tubs weekly. Phyllosoma that were starved during stages I and II received the same daily procedure except they were not fed. Larvae starved in stage II had been fed in stage I. The number of larvae added to the tubs was estimated volumetrically, and larvae were randomly stocked at approximately 1,500/tub.

Artemia

Phyllosoma were fed with *Artemia* (Great Salt Lake) that had been on-grown for 4–5 days, after reaching instar II, using Algamac 2000 (Biomarine, Aquafauna) and an *Isochrysis* marine algal concentrate (Reed Mariculture, San Jose, CA). *Artemia* were also enriched for 18 h (two feedings, 1600 and 0200) with Algamac 2000 prior to feeding to the phyllosoma.

Sampling Protocol

All phyllosoma samples for biochemical analysis were taken in triplicate (i.e., three tubs were used for each sample). For stage I analyses, phyllosoma were sampled at hatch (day 0), fed and starved samples in the middle of stage I (day 6), and a sample of fed larvae after molting at the beginning of stage II (day 15). For stage II analysis, phyllosoma were sampled at hatch (day 0), at the beginning of stage II (day 15), fed and starved samples were taken in the middle of stage II (day 20), and a sample of fed larvae after molting at the beginning of stage III (day 26). Larval stages were measured from the anterior margin of the cephalic shield between the eyestalks to the posterior of the abdomen and staged according to Braine et al. (1979). Samples of enriched *Artemia* were taken for analysis.

Lipid Analysis

Lipid Extraction

Phyllosoma and *Artemia* samples were filtered onto 47-mm Whatman GFC filters and washed with 0.5 M ammonium formate. Samples were stored at -80°C, freeze-dried overnight, and weighed to determine dry mass (DM). Samples were quantitatively extracted overnight using a modified Bligh and Dyer (1959) one-

phase methanol:chloroform:water extraction (2:1:0.8 v/v/v). The phases were separated the following day by the addition of chloroform and water to give a final solvent ratio of 1:1:0.9 v/v/v methanol:chloroform:water. The total solvent extract (TSE) was concentrated using a rotary evaporator at 40°C, blown down to dryness under nitrogen, and weighed to determine the total lipid content. Samples were made up in a known volume of chloroform and stored at -20°C before analysis.

Lipid Classes

To quantify individual lipid classes (LC), an aliquot of the TSE was analyzed using an Iatroscan MK V TH 10 thin-layer chromatography-flame ionization detector (TLC-FID) (Iatron Laboratories, Tokyo, Japan). Samples were applied in duplicate to silica gel SIII chromarods (5-µm particle size) using 1-µL disposable micropipettes. Chromarods were developed in a glass tank lined with pre-extracted filter paper. The primary solvent system used for lipid class separation was hexane:diethyl ether:acetic acid (60:17:0.1 v/v/v), a mobile phase resolving nonpolar compounds such as wax esters (WE), triacylglycerols (TAG), free fatty acids (FFA), and sterols (ST). A second nonpolar solvent system of hexane:diethyl ether (96:4 v/v) was also used to resolve hydrocarbons (HC) from WE, and TAG from diacylglycerol ether (DAGE). After development, the chromarods were oven-dried and analyzed immediately. The FID was calibrated for each compound class (phosphatidylcholine, cholesterol, cholesteryl ester, oleic acid, squalene, TAG [derived from fish oil], WE [derived from fish oil] and DAGE [derived from shark oil], 0.1–10 µg range), and the peaks were quantified using DAPA software (Kalamunda, Western Australia).

Fatty Acids

An aliquot of the TSE was *trans*-methylated to produce fatty acid methyl esters (FAME) using methanol:chloroform:conc. hydrochloric acid (10:1:1 v/v/v) at 80°C for 2 h. The FAME produced were extracted into hexane:chloroform (4:1 v/v, 3 × 1.5 mL), reduced under nitrogen to dryness, and treated with *N,O*-bis-(trimethylsilyl)-trifluoroacetamide (BSTFA, 100 µL, 70°C, overnight) to convert ST and alcohols to their corresponding TMSi (trimethylsilyl) ethers. Samples were blown down under nitrogen and an internal standard (C19 and C23, 40 mg/g) was added.

Gas chromatographic (GC) analyses were performed with a Hewlett Packard 5890A GC (Avondale, PA) equipped with a HP-5 cross-linked methyl silicone fused silica capillary column (50 m × 0.32 mm i.d.), a FID, a split/splitless injector, and a HP 7673A auto sampler. Helium was used as the carrier gas. Samples were injected in splitless mode at an oven temperature of 50°C. After 1 min, the oven temperature was raised to 150°C at 30°C/min, then to 250°C at 2°C/min, and finally to 300°C at 5°C/min. Peaks were quantified with Waters Millennium software (Milford, MA). Individual components were identified using mass spectral data and by comparing the retention time data with those obtained for authentic and laboratory standards. GC results are subject to an error of ±5% of individual component area. GC-mass spectrometric (GC-MS) analyses were performed on a Finnigan Thermoquest GCQ GC-mass spectrometer (Austin, TX) fitted with an on-column injector. The GC was fitted with a capillary column similar to that described above.

Statistical Analysis

Results were analyzed using one-way ANOVA with Tukey's test used for multiple comparisons. Percentage data was arcsine√

transformed and gravimetric data \sqrt{v} transformed to make the data normal and homogenous. When two samples were compared (batch sizes), a *t*-test was used. Statistical analyses were performed using Statistica software (StatSoft Inc., Tulsa, OK, version 6). Data is presented as mean \pm SD, and results were considered significantly different at $P \leq 0.05$.

RESULTS

Larvae from the two batches did not significantly differ in DM or lipid content (mg/g DM and $\mu\text{g}/\text{phyllosoma}$) at hatch; however, the lipid content was slightly elevated in larvae from the second hatch. For stage I samples, changes in fed and starved larvae were compared with newly hatched larvae (from first hatch), and for stage II samples to newly molted stage II larvae (from the second hatch).

Phyllosoma and Lipid Amounts

By mid stage, the DM had increased in stage I and II (significant) fed larvae (16.5 and 33.6%, respectively) and conversely decreased in starved stage I (significant) and II larvae (29.1 and 10.9%, respectively) (Table 1). Larvae also showed increases in dry mass (DM) by the time they molted to the next stage (Table 1). As with DM, the lipid content (mg/g DM and $\mu\text{g}/\text{phyllosoma}$) of stage I and II larvae increased in fed samples and decreased in starved samples (Table 1). In stage I larvae, the increase in lipid content of fed larvae accounted for 6.2% of the increase in DM whereas the lipid decrease in starved larvae accounted for 6.7% of the decrease in DM. In stage II larvae, lipid accounted for a much greater percentage of the increase in DM of fed larvae, 19.2%, and also accounted for a much larger portion of the decrease in starved stage II larvae, 35.0%. Although newly molted stage III did have a similar amount of lipid/phyllosoma compared with fed stage II larvae, total lipid (mg/g DM) decreased significantly after the molt (Table 1).

Lipid Class

In all phyllosoma samples, polar lipid (PL) was the major LC (82.0–94.3%) (Table 2). As with lipid amounts, PL concentration in larvae differed from the different hatches, larvae from the second hatch (49.1 mg/g DM) having significantly increased levels compared with larvae from the first hatch (37.6 mg/g DM) (Table

2, Fig. 1). PL was also the major LC used during starvation and on an absolute basis was significantly reduced in starved stage I and II larvae (Table 2, Fig. 1). The amount of PL in starved stage I larvae (27.2 mg/g DM) was 27.6% less than in newly hatched larvae (37.6 mg/g DM), and increased by 8.4% in fed phyllosoma (40.8 mg/g DM) (Fig. 1). For stage II larvae, the amount of PL in starved larvae (29.1 mg/g DM) was 53.9% less than in newly molted stage II larvae (63.0 mg/g DM), and increased by 50.2% in fed stage II larvae (94.7 mg/g DM) (Fig. 1). In both stages, the increase in PL (mg/g DM) almost solely accounted for the increase in lipid (mg/g DM). ST were the next most abundant lipid class (largely cholesterol) comprising between 5.1–12.1% of the total lipid (Table 2). In relative proportions, ST levels (%) increased in starved larvae (significant in stage II), with no significant decrease in amount (mg/g DM) (Table 2, Fig. 1). HC were the next most abundant LC (0.4–4.6%), followed by WE (0.1–2.3%), FFA (0.1–1.1%), DAGE and TAG ($\leq 0.2\%$) (Table 2).

Enriched *Artemia* contained high relative and absolute levels of PL (62.0%; 83.9 mg/g DM), although unlike the phyllosoma samples, also had high levels of TAG (31.0%; 41.8 mg/g DM). This was followed by ST (3.3%; 4.5 mg/g DM), and FFA (3.1%; 4.2 mg/g DM), with HC, DAGE, and WE being minor components ($\leq 0.3\%$; < 0.5 mg/g DM) (Table 2, Fig. 1).

Fatty Acids

Gravimetrically, newly hatched larvae from the second hatch were significantly elevated in total FA and all the major FA compared with the first hatch (Tables 3 and 4, Fig. 2). Of the 55 fatty acids (FA) identified, 18 individual FA had some concentrations $\geq 1\%$ in the phyllosoma samples. The six most abundant FA ($\geq 5\%$) were 20:5n-3 (EPA, 13.7–21.3%), 16:0 (palmitic acid, 10.7–15.2%), 18:1n-9c (oleic acid, 10.6–14.6%), 22:6n-3 (DHA, 7.1–13.0%), 20:4n-6 (arachidonic acid, AA, 5.8–12.4%), and 18:0 (stearic acid, 8.5–13.9%) (Tables 3 and 4). These six components generally accounted for between 68.6 to 76.9% of the total FA.

The major FA in fed stage I larvae showed similar relative contributions to newly hatched larvae, except there was a significant increase in EPA and decrease in 16:0 (Table 3). Similarly, fed stage II larvae showed a similar relative contribution of the major FA compared with newly molted stage II larvae, although 16:0 was significantly elevated (Table 4). Gravimetrically, total FA (mg/g DM) increased significantly in fed stage I and II larvae as did the

TABLE 1.

TAG, triacylglycerol; DAGE, diacylglycerols ether.

major FA (Fig. 2). The sum of saturated fatty acids (SFA) and monounsaturated fatty acids (MUFA) in fed stage I and II larvae did not change. The sum of polyunsaturated fatty acids (PUFA) did not significantly change in fed stage I and II larvae, however there was a small increase (Table 3 and 4). Both stage I and II fed larvae showed an increase in n-3/n-6 ratio (significant in stage I) (Tables 3 and 4). The EPA/AA ratio showed a significant increase in both fed stage I and II larvae, largely due to an increase in EPA for stage I, and a decrease in AA, particularly for stage II larvae (Tables 3 and 4). The DHA/EPA ratio did not significantly change in fed stage I or II larvae.

Starved stage I and II larvae showed a gravimetric decrease in total FA, although this was only significant in stage II larvae (Tables 3 and 4). Individually, most of the major FA decreased in starved stage I larvae, although only DHA decreased significantly, and 18:0 actually increased (Fig. 2). In starved stage II larvae, all the major FA significantly decreased gravimetrically. On a percentage basis, AA increased in starved stage I and II larvae (sig-

nificant in stage II), with no significant change in EPA and DHA (Table 3 and 4). Starved stage I larvae showed no significant difference in the sum of MUFA or PUFA compared with newly hatched larvae, however SFA significantly increased (Table 3). Starved stage II larvae did not show a difference in the sum of SFA, however PUFA significantly increased and MUFA significantly decreased (Table 4). In stage I and II starved larvae, there was no change in the n-3/n-6 ratio (Tables 3 and 4). A reduction in the EPA/AA ratio was observed in starved larvae (not significant), with the DHA/EPA ratio not changing (Tables 3 and 4).

The total FA content significantly decreased in newly molted stage III larvae compared with fed stage II larvae. However, newly molted stage II larvae actually contained a higher total FA content than fed stage I larvae (Table 3 and 4).

The percentage FA composition of the *Artemia* was dominated by 16:0 (19.7%), followed by DHA (14.3%), 18:1n-9c (12.3%), EPA (10.7%), 18:1n-7c (9.8%), and 16:1n-7c (6.2%). Other FA were present at $\leq 6\%$, with AA at 2.3% (Table 3). Phyllosoma were able to

accumulate AA and EPA at percentage levels above that in *Artemia*, but not DHA, which was always lower in phyllosoma.

DISCUSSION

Changes in Phyllosoma Dry Mass and Lipid Content

In both larval stages, there were increases in the DM and in the amount of lipid in fed larvae, with decreases in starved larvae. Changes were more significant in stage II larvae (Table 1). Lipids are used during starvation in other crustaceans (Virtue et al. 1993), and previous research has found lipid a key component in larval stages of spiny lobsters (Jeffs et al. 1999, Phleger et al. 2001). However, lipid only accounted for 6.5% of the decrease in DM in starved stage I larvae whereas this increased to 35.0% for stage II larvae. Also, lipid only accounted for 6.2% of the increase in DM of fed stage I larvae, increasing to 19.7% in stage II larvae. This indicates that lipid was not the major nutrient catabolized during starvation or accumulated by the feeding phyllosoma. Smith et al.

(2003) suggested that protein, and to a lesser extent carbohydrate, would have been preferentially catabolized during starvation of stage I *J. edwardsii* phyllosoma in which lipid accounted for 17.8% in the loss of DM. This higher value in *J. edwardsii* may be related to the larger size of stage I larvae compared with *P. cygnus*. D'Souza (1998) found starved *Penaeus japonicus* and *Penaeus monodon* larvae exhibited gravimetric decreases in both lipid and protein.

Larvae molting to successive stages showed an increase in DM, with stage II larvae molting to stage III also showing a reduction in the lipid content (Table 1), possibly used during the molt. Smith et al. (2003) suggested that the increase in lipid accumulation seen in fed *J. edwardsii* phyllosoma might be used during the subsequent moult, as found with American lobster (*Homarus americanus*) larvae (Sasaki 1984). A decrease was not seen in newly molted stage II *P. cygnus* larvae compared with fed stage I, the lipid level was actually higher in the newly molted stage II larvae (Table 1). This may be attributable to a large variation in the

molting period of the larvae. Larvae from the first hatch took 3 days to all molt to stage II before a sample was taken. Therefore, many of the sampled larvae may have started to accumulate lipid.

Lipid Class

Variation Between Hatches and Species

Newly hatched larvae from the second hatch had elevated concentrations of lipid (PL and total FA) compared with larvae from the first hatch, with larvae from the second hatch also being significantly larger (Tables 1, 2, 3, and 4). This may be attributable to different temperatures during egg incubation. Both females extruded eggs at 25°C, however eggs from the first hatch were incubated in water at 22°C whereas those from the second hatch were at 19°C. Smith et al. (2002) found newly hatched *J. edwardsii* phyllosoma from warmer water were significantly smaller. The warmer incubation temperature may have resulted in more energy being used for metabolism and less for development of the em-

bryo. This difference at hatching between batches of *P. cygnus* larvae had become significant at the molt to stage II (Table 1). Larvae from the second hatch showed significantly higher lipid content (PL and total FA), suggesting the condition of larvae at hatch affected their condition into stage II, and possibly for further culture.

The absence or very low levels of TAG in phyllosoma samples has been a common feature found in studies so far (Nelson et al. 2003, Phleger et al. 2001), including this study (Table 2). TAG is generally the most common storage lipid in animals, used as a short-term energy reserve, and it is generally catabolized primarily during starvation (Koven et al. 1989, Olsen 1998, Phleger et al. 2001). This is in contrast to PL, which plays an important structural role and is usually preferentially conserved (Koven et al. 1989). PL was the major LC in *P. cygnus* larvae comprising 82.0–94.3% of the total lipid from all samples (Table 2), as found with *J. edwardsii* phyllosoma (Nelson et al. 2003, Phleger et al. 2001). In this study, the increase found in lipid (mg/g DM) in both stages

Figure 2. The content of major fatty acids (mg/g DM) at hatch, after feeding, starvation, and molting ($n = 3$) of western rock lobster (*Panulirus cygnus*) phyllosoma and in enriched *Artemia*. FA, fatty acid; DM, dry mass; AA, arachidonic acid; EPA, eicosapentaenoic acid; DHA, docosahexaenoic acid.

of fed *P. cygnus* larvae corresponded almost completely to the increase in PL (mg/g DM). The use of PL as the dominant storage medium in the puerulus stage of rock lobsters is unlike many other marine taxa, including crustacea, which tend to use TAG and WE (Jeffs et al. 2001, Sasaki 1984). Jeffs et al. (2001) found PL reserves were primarily used during the puerulus stage of *J. edwardsii* and suggested the use of PL as a storage medium in the puerulus may be related to its characteristic transparency, an important feature of this nektonic stage that is highly vulnerable to pelagic visual predators. Jeffs et al. (2001) suggested pueruli avoid storing neutral lipid because of its opaque nature. The prevalence of PL as the major LC in phyllosoma larvae may also be due to their transparency, which could provide protection during their long larval ocean phase.

PL was also the major LC used during starvation and was significantly reduced in starved larvae from both stages (Table 2, Fig. 1). Lipid was found to be the primary energy source used during the nonfeeding puerulus stage and PL was also the major LC used (Jeffs et al. 1999, Jeffs et al. 2001). PL was also the only LC to be depleted when stage II larvae molted to stage III, with a significant gravimetric reduction (Fig. 1).

ST (mainly cholesterol) was the next most abundant LC in the phyllosoma samples (Table 2). PL, together with cholesterol and sphingolipids, are omnipresent components of cell membranes and are therefore both structurally and functionally important (Olsen, 1998). Unlike PL, relative amounts of ST increased in starved larvae, with no significant decrease in gravimetric amount (mg/g DW) (Table 2, Fig. 1). This retention may indicate the importance of ST, as ST are used not only in membranes but also in the transport of lipids (Ackman 1998).

Phyllosoma were able to maintain a higher percentage of PL and ST than found in their diet (Table 2). *Artemia* contained lower levels of PL (62.0%) and ST (3.3%), with higher levels of TAG (31.0%) and FFA (3.1%) than phyllosoma (Table 2). It appears PL and ST are important nutrients to the phyllosoma, hence their

accumulation at levels (%) above that found in their food. However, TAG is almost absent (<0.2%) in the phyllosoma samples (Table 2).

The phyllosoma lipid was around 90% PL, and comparatively the PL in *Artemia* was much lower (60%). TAG makes up a large portion in *Artemia*, and it is possible that phyllosoma cannot absorb or accumulate the TAG as efficiently as PL to gain nutrients.

Fatty Acids

The major FA and their profiles in newly hatched *P. cygnus* larvae (Tables 3 and 4) are similar to those reported for newly hatched *J. edwardsii* phyllosoma (14.2–14.6% 16:0, 12.6–13.3% 18:1n-9c, 6.9–7.1% 18:0, 11.6–11.9% AA, 14.8–15.3% EPA, and 7.6–8.1% DHA; Phleger et al. 2001). Fed *P. cygnus* larvae also showed a similar relative contribution from the major FA, with all the major FA significantly increasing gravimetrically. However, the relative levels were different to those found in their diet. The FA distribution of animals is believed to be primarily determined by the composition of their dietary FA (Napolitano 1998, Olsen 1998). In comparison, for the current study 16:0 and DHA were at lower relative levels than found in the *Artemia*, with 18:0, AA, and EPA at levels above that found in the *Artemia*, possibly indicating a preferential accumulation of these FA. DHA showed a continual reduction in relative contribution as the phyllosoma developed (fed and molting samples). This may suggest that the DHA was not in a form that the phyllosoma could absorb and use or was not at high enough levels. Nichols et al. (2001) examined a wide range of potential prey items for *J. edwardsii* phyllosoma and found that DHA was in average 26%, markedly higher than that in the *Artemia*. The prey also contained on average 77% PL, again far greater than occurring in *Artemia*. AA also declined throughout development; however the level of AA in the *Artemia* was always much lower than found in the phyllosoma.

The increase in the EPA/AA ratio in fed larvae suggests a higher accumulation of EPA in fed larvae, however, starved larvae

did exhibit a reduced ratio (not significant) suggesting more AA was conserved during starvation (Table 3 and 4). The DHA/EPA ratio did not show major changes in fed or starved stage I or II larvae, although some were statistically significant, suggesting both FA were used/retained at a similar rate (Tables 3 and 4).

To formulate a diet that meets the essential fatty acid (EFA) requirements of a given species, it is necessary to know the dominant EFA series for this species (Corraze 2001). Experiments have found that during starvation larvae conserve important FA, with starvation suggested as one way to determine nutritional requirements of larvae (Koven et al. 1989, Olsen 1998). Starved *P. cygnus* larvae showed a gravimetric decrease in total FA, however, a number of individual FA showed no change or assumed a greater ranking in the FA profile, possibly signifying a greater degree of importance. The FA changes were however dependent on the stage tested. The relative contribution of AA increased in starved stage I and II larvae, although the change in starved stage I larvae was not significant. EPA and DHA showed increases in stage II larvae, however, in starved stage I larvae there was a small decrease. D'Souza (1998) found PUFA (AA, EPA and DHA) were conserved in starved *Penaeus* larvae and suggested this was most likely due to their primarily structural role.

Starved stage I larvae showed a significant increase in SFA, with no change in MUFA or PUFA. However, in starved stage II larvae, MUFA significantly decreased whereas PUFA significantly increased, possibly indicating a preferential use of MUFA during starvation and a sparing or retention of PUFA. Kattner et al. (1994) found the FA profile of larval caridean shrimp also showed major

differences dependent on stage and larval sample. The variation in results in the present study suggest a response for *P. cygnus* which is dependent on the stage of the larvae.

CONCLUSIONS

Although lipid was not a major component of the larvae and was not the major nutrient accumulated in fed larvae or used in starved larvae, lipid became a greater component in stage II larvae compared with stage I larvae, suggesting that lipid likely assumes a greater importance as larvae progress through developmental stages. Further studies should also assess the importance of other nutrients (i.e., protein and carbohydrate) in phyllosoma development. The LC profile of the phyllosoma samples was dominated by PL. PL was also the main LC used during starvation and accounted for almost the entire increase in lipid in fed larvae. ST was the next most abundant LC and showed an increase in relative contribution in starved larvae, its retention possibly related to its important structural/function role. *Artemia* had high levels of TAG, however phyllosoma never accumulated TAG. The FA changes occurring in larvae appeared to be stage dependent, however PUFA, such as AA, EPA and DHA, were generally conserved (particularly in stage II larvae). Results from the current study provide information that will assist in formulating diets for phyllosoma culture. Larval feeds containing lipids rich in EFA (EPA, DHA and AA) and in a form allowing them to synthesize PL may be more suitable for future research with *P. cygnus*. The *Artemia*, as enriched in this study, do not meet these criteria, with current work to focus on enriching *Artemia* to make them reflect the perceived profile.

PREDICTING THE EFFECTS OF A CHANGING COASTAL LANDSCAPE ON LARGE-SCALE CLAMAQUACULTURE. Gretchen L. Arnold, Mark W. Luckenbach, Harry V. Wang, and Jian Shen, Eastern Shore Laboratory Virginia Institute of Marine Science College of William and Mary Wachapreague, VA 23480, USA. E-mail: gretchen@vims.edu

Hard clam (*Mercenaria mercenaria*) production in the lower Chesapeake Bay, Virginia, USA has increased dramatically in the last decade. Cultured clams are densely planted in shallow zones adjacent to land, often in small embayments or tidal creeks, where land use, water quality, and bivalve production are closely linked through nutrient and phytoplankton dynamics. Meanwhile, the coastal agricultural and forested lands in this region are under increasing development pressure. This changing land use has the potential to impact clam aquaculture by changing loadings of nutrients, bacteria, suspended sediments, and fresh water delivered to estuaries, resulting in altering primary production.

In an effort to examine the links between land use, water quality, and hard clam aquaculture production in these systems, we have initiated a large-scale modeling and field verification effort. The project is linking several sub-models: (1) a basin-level watershed loading sub-model; (2) a physical transport-based water quality sub-model; (3) a sediment suspension/resuspension sub-model; (4) a clam physiology sub-model; and (5) an aquaculture production sub-model into an integrated modeling framework. The framework as a whole will be calibrated and verified by field data and then used to estimate carrying capacity under current conditions and provide predictions under alternative development scenarios. This project is being conducted in Cherrystone Inlet, a tidal creek in the lower Chesapeake Bay with an estimated standing stock of 80 million cultured clams.

In this portion of the study we examine how specific land-use management decisions would affect estuarine water quality and exploitation carrying capacity for clam aquaculture in Cherrystone Inlet. The results will provide local government with a basis for evaluating how effects of zoning decisions may affect the aquaculture industry, provide the aquaculture industry with an estimate of exploitation carrying-capacity for the system, and begin to describe the ecological interactions between large-scale clam aquaculture, primary production, and land use.

MITOCHONDRIAL GENETIC VARIABILITY OF CULTURED VERSUS WILD NORTHERN HARD CLAMS *MERCENARIA MERCENARIA*. Patrick Baker, Claudia Rocha, Brian Bowen, Paolete Soto, Luiz Rocha, and Leslie Sturmer, Fisheries and Aquatic Sciences, University of Florida, Gainesville, FL 32611, USA. E-mail: pbaker@mail.ifas.ufl.edu

Aquaculture of northern hard clams, *Mercenaria mercenaria*, is a significant industry in Florida, USA. Hard clams are grown to market size in shallow coastal plots, but seed stocks are produced

in commercial hatcheries. Hatchery stocks are usually selected for the *notata* strain, a desirable shell color variation with no other known performance advantages. Concern was raised that hatchery-breeding practices could reduce genetic variability, and hence, potentially reduce performance, compared with wild stocks. To evaluate this concern, mitochondrial cytochrome oxidase I (COI) sequences (542 bp) were generated from five Florida hatchery stocks and in clams escaped from aquaculture in west Florida. The mtDNA diversity in captive strains was compared to wild stocks from east Florida, Georgia, and New York. *M. campechiensis*, a morphologically similar, sympatric congener, sometimes occurred in samples but showed about 1%–1.5% Tamura-Nei genetic distance from *M. mercenaria* and was removed prior to statistical analysis. High haplotype diversity was found in COI sequences for all wild populations and some hatchery stocks (Table 1). Some hatchery stocks still showed levels of genetic variability within the typical range for a marine bivalve, but two had significantly reduced haplotype diversity. Two hatcheries also had apparent contamination with *M. campechiensis*. These findings indicate reduced diversity in some hatcheries, but others managed to avoid depletion of genetic resources. Further surveys with microsatellite DNA are mandated to assess inbreeding and the comparative performance of breeding stocks.

TABLE 1.
Genetic variability in wild and hatchery stocks of
Mercenaria mercenaria.

Locality/stock	Haplotype diversity	Nucleotide diversity
Southeast Florida Wild	0.93 ± 0.12	0.006 ± 0.004
Northeast Florida Wild	0.75 ± 0.09	0.005 ± 0.003
Georgia Wild	0.84 ± 0.09	0.005 ± 0.003
New York Wild	0.80 ± 0.11	0.004 ± 0.003
Hatchery I	0.78 ± 0.15	0.004 ± 0.003
Hatchery II	0.33 ± 0.21	0.0006 ± 0.0008
Hatchery III	0.50 ± 0.05	0.003 ± 0.002

SELECTIVE BREEDING TO IMPROVE RESISTANCE AGAINST SUMMER MORTALITY IN THE PACIFIC OYSTER *CRASSOSTREA GIGAS*: RESULTS AFTER 3 GENERATIONS. Pierre Boudry, Lionel Dégremont, Edouard Bédier, and Jean François Samain, Laboratoire IFREMER de Génétique et Pathologie, Ronce les Bains, 17390 La Tremblade, France. E-mail: Pierre.Boudry@ifremer.fr

Summer mortality of adults and juveniles has been reported in the Pacific oyster, *Crassostrea gigas*, for many years and in several countries. The French multidisciplinary program "Morest" aims to investigate the causes of the summer mortality in *Crassostrea gigas*. Within this program, we designed multi-site field

experiments to assess to what extent genetic variability exists for summer mortality in French populations of *C. gigas* and to determine whether selective breeding could improve survival.

The first generation was based on 3 sets of bi-parental families, following a nested half-sib crossing design. Progenies (G1): 17 half-sib families (HSF) were placed in three sites along French coasts in February, March, and April 2001 and reared following usual practices until October 2001. A large variation among HSF was observed (Fig. 1). Heritability estimates for survival were very high (mean $h^2 = 0.81 \pm 0.29$). In 2002, 3 "good" HSF and 3 "bad" HSF were selected on their survival performances to constitute a second generation (G2) by divergent selection. Additionally, these were also crossed to make inbred families. Both inbred and outbred families, reared similarly to the first generation, showed a good response to selection (realized heritabilities >0.7) (Fig. 2). No significant effect was observed on growth performance of the selected families. In 2003, a third generation of inbred and outbred families was produced to confirm the results obtained in 2002. Globally, our results indicate that selective breeding programs can efficiently improve survival of juvenile oysters.

Figure 1. Variation of mean mortality among HSF in the G1 ($P < 0.001$).

FRESHWATER MOLLUSCS OF THE WESTERN UNITED STATES: WHERE ARE WE TODAY, AND WHERE ARE WE GOING? Jayne Brim Box and Jeff Kershner, USDA Forest Service Rocky Mountain Research Station, 860 N 1200 E., Logan, UT 84321, USA. E-mail: brimbox@comcast.net

The western states contain at least six endemic mussel species, and many endemic snail species. Records of western freshwater mollusks date from the mid 1800s, but there is a dearth of current

information on the distribution and abundance of western freshwater mollusks, in part because a comprehensive survey throughout their distributional ranges has not been done. There is also confusion regarding the taxonomic status of western species, and the exact number of valid species that occur in the region is not clear. Although several western states recognize that mollusk populations are declining, conservation and recovery efforts are hampered by the lack of basic information on western mollusk genetics, zoogeography, systematics, and host fish. In addition, the conservation status for most western mollusks is unknown. The objectives of our work were to produce a database of all western freshwater mollusk species and their historical distributions, produce a synonymy of western freshwater mollusks that includes all previously described western species, compile a georeferenced distributional database for all western mollusk mussels, and to conduct additional field surveys, host fish analyses, and genetic work. Data on historical occurrences, habitat, life history, and other information on western mollusks were entered into a relational database. Distributional data were georeferenced, and special attention was given to nomenclature issues in order to determine whether some of the previously described western species deserve species-level status. To date, approximately 1,000 records of unionid mussels and 1,400 records of freshwater gastropods have been compiled from over 180 publications and museum records. These data were augmented by current field studies conducted in five western states. We also conducted an intensive genetic survey of western mussel populations to describe patterns of phylogeny and gene flow. The results of our studies raise intriguing questions about taxonomy, reproduction, gene flow, and host fish requirements in western mollusk species.

BIOCHEMICAL CHANGES IN JUVENILE HARD CLAMS *MERCENARIA MERCENARIA* IN RESPONSE TO HEAT AND COLD SHOCK. Nicole T. Brun, Neil W. Ross, V. Monica Bricelj, Alaina R. Boyd, and Thomas H. MacRae, Dalhousie University and the National Research Council, Institute for Marine Biosciences, Halifax, Nova Scotia Canada B3H 3Z1. E-mail: Nicole.Brun@nrc-cnrc.gc.ca

In Atlantic Canada, there has been a continuing interest in the development of hard clam *Mercenaria mercenaria* aquaculture. There are, however, limitations and challenges for such an industry in this region, because it represents the northern limit of the distributional range of *M. mercenaria*. Recently, juvenile hard clams have suffered heavy mortalities during over-wintering in Atlantic Canada. An important factor, thought to be associated with the latter, is the health status of the animals on entering the over-wintering period, and/or a combination of acute and chronic thermal stress experienced during the winter months, when the animals are unable to feed. Because there is very limited information on the physiology of juvenile *M. mercenaria* at low temperatures, espe-

cially below 12 °C, the exact causes and mechanisms of the observed over-wintering mortalities and its prevention deserve further attention.

Heat shock proteins (HSPs) are ubiquitous, highly conserved, and have been shown to increase on exposure to various stressors, including temperature. HSP expression has been well characterized in mussels, but limited information is available for other bivalves, such as hard clams. Cold shock Stress protein response (SPR) has not been previously investigated in bivalves. Characterization of the SPR to acute temperature shock may have application in acquired thermotolerance of hard clams transferred from hatchery to field grow-out sites.

Experiments were conducted to examine whether, and to what extent rapid temperature increases and/or drops induce a SPR in hard clams, and to examine HSP expression in hard clams under laboratory-simulated over-wintering conditions. The SPR to acute heat shock (20 °C to 30 °C for 3 h) and acute cold shock (20 °C to 3 °C for 3 h), determined by HSP70, was examined in juvenile *M. mercenaria* (Fig. 1). HSP70 decreased significantly during heat shock, but slowly increased during recovery period and exceeded control levels after 24 h. Interestingly, cold shock also modulated HSP70 expression. HSP70 increased significantly, with levels still rising after 24-h recovery. Experiments designed to simulate over-wintering conditions in juvenile hard clams are ongoing, and preliminary results reveal no increase in HSP70 expression clams subjected to a 3-h cold shock from 12 °C to 1 °C. The results of this study are currently being used to validate other biochemical indicators, such as proteases, and preliminary results on the latter will be presented.

IDENTIFICATION OF A HERPES-LIKE VIRUS IN PACIFIC OYSTERS FROM TOMALES BAY, CALIFORNIA. Colleen A. Burge, Robyn M. Estes, Nancy A. Stokes, John S. Hargrove, Bruce J. Barber, Ralph A. Elston, Eugene M. Burreson, Kimberly S. Reece, and Carolyn S. Friedman, School of Aquatic and Fishery Sciences, University of Washington, 1122 NE Boat Street, Seattle, WA 98195, USA. E-mail: cab3@u.washington.edu

Beginning in 1993, large-scale losses of Pacific oyster seed have been observed in Tomales Bay, California. These losses have been attributed to multiple environmental stressors including elevated water temperatures and phytoplankton blooms. An oyster herpes-like virus infecting various species of oyster larvae and juveniles was first described in French and New Zealand hatcheries in 1992 and was associated with high mortality rates. Given the timing and scope of the Pacific oyster seed mortalities in conjunction with elevated seawater temperatures associated with these declines, we conducted a preliminary assessment of the contribution of this infectious agent in these losses. Due to the importance of this viral agent to international trade, we examined the host and geographic distribution of this possible oyster pathogen in many locations in the United States. Although only recently observed in Pacific oysters, we sampled eastern (*Crassostrea virginica*), pacific (*C. gigas*) and Suminoe (*C. ariakensis*) oysters for presence of the herpes virus using molecular and histologic methods from Maine, Virginia, Florida, Louisiana, California (Tomales Bay), Oregon, and Washington. A polymerase chain reaction (PCR) method based on published sequence information was validated and optimized for use in these studies. Positive control material was kindly provided to us by collaborators from IFREMER (T. Renault).

Only Pacific oysters sampled from Tomales Bay, CA in the summer of 2002 were infected by the herpes-like virus as evidenced by PCR analysis. However, no clear microscopic confirmation of herpes-like nuclear inclusions has been observed to date. Sequence analysis determined that the virus is nearly identical to the virus observed in oysters and clams reared in France. These data suggest that further studies be warranted. We are in the process of further examining the influence of this virus on oyster survival in Tomales Bay, California.

LINE-CROSSING WITHIN AND AMONG FIVE COMMERCIAL STRAINS OF HARD CLAMS, *MERCENARIA MERCENARIA*: GROWTH, SURVIVAL, AND SUSCEPTIBILITY TO QPX DISEASE AT DIFFERING SALINITIES. Mark D. Camara, current address: Hatfield Marine Science Center, USDA/ARS Aquaculture Genetics, 2030 SE Marine Science Dr., Newport, OR 97365, USA. E-mail: Mark.Camara@oregonstate.edu; Lisa M. Ragone Calvo, Ryan B. Carnegie, and Standish K. Allen Jr., Aquaculture Genetics and Breeding Technology Center, Virginia Institute of Marine Science, Gloucester Point, VA 23062, USA.

Cultured hard clams, *Mercentaria mercenaria*, are a multi-million dollar industry in Virginia, USA. Field grow-out sites vary from full ocean salinity on the eastern shore of the Chesapeake

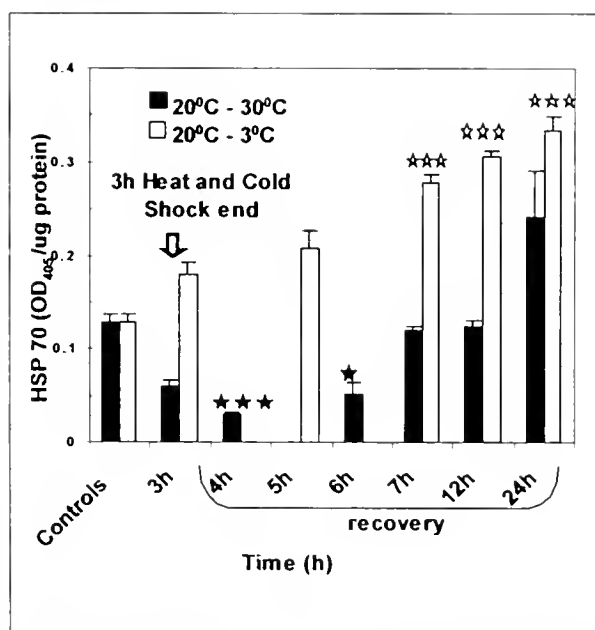

Figure 1. HSP70 expression in juvenile hard clams to acute heat (■) and cold (□) shock. $P < 0.05$.

Bay to mid-salinity estuarine sites within the bay. Quahog parasite unknown disease (QPX) has recently emerged as the causal agent of sporadic catastrophic mortalities at high salinity sites. This disease first appeared in the 1950s in New Brunswick Canada. From the late 1980s through the mid 1990s, QPX was found in Massachusetts, New Jersey, and Virginia, and first caused economically important mortalities in Virginia in 2001. QPX has the potential to threaten a large portion of the cultured clam industry on the eastern coast of the USA if the problem continues to worsen. At present, the industry depends heavily on hatchery production of essentially undomesticated genetic stocks. Relatively little is known about the suitability of stocks to different environmental conditions or their susceptibility to QPX, but previous studies indicate that stocks originating from more southern populations are more susceptible to the parasite that causes QPX.

We therefore evaluated how different commercially available clam strains perform along a salinity gradient in Virginia and the potential for enhancing growth performance and QPX resistance by outcrossing among strains. We first created all 15 possible combinations within and among five brood stock strains in the hatchery. We subsequently raised the juveniles in common conditions until they reached approximately 10 mm, at which point we split the groups for planting at five sites encompassing the range of salinities at which clams are commercially grown. We monitored their growth in the hatchery and the field and at the high salinity sites where QPX is expected to be found; we sub-sampled each group to estimate the prevalence of QPX disease within groups using standard histopathologic techniques. We then compared the growth and QPX susceptibility of groups, estimated the correlations among performance measures between life stages, compared the performance and QPX prevalence of within- and among-strain crosses, and assessed how performance measures varied among environments. We discuss the results and their implications for strain selection, hatchery-spawning procedures, and future efforts in selective breeding for superior hard clam strains.

IMPROVEMENT OF DISEASE RESISTANCE AND UNDERSTANDING OF SUMMER MORTALITY IN PACIFIC OYSTERS *CRASSOSTREA GIGAS*. Daniel Cheney, Louis Burnett, Aimee Christy, Jonathan Davis, Ralph Elston, Carolyn Friedman, Fred Griffin, Christopher Langdon, and Andrew Suhrbier, Pacific Shellfish Institute, 120 State Ave., NE #142, Olympia, WA 98501, USA. E-mail: psi@pacshell.org

Pacific oyster (*Crassostrea gigas*) summer mortalities are a recurring problem in the United States, Japan, France, and Mexico. During the 2002 to 2003 growing season, for example, farmers in Carlsbad, CA, Netarts Bay, OR, and Willapa Bay and south Puget Sound, WA reported up to a 50% loss of market-ready oysters occurring over a brief 2 to 3 week span (see Fig. 1 of oyster

cluster). Research findings indicate genetic pedigree, ploidy, culture practice, and prior exposure to environmental stress have varying influences on the expression of the summer mortality disease in Pacific oysters. Key facets of research to date include (1) the ability of oysters to survive episodes of summer mortality is in part genetically determined and perhaps can be enhanced through selective breeding of families showing high survival traits. Pedigreed lines of oysters with different genetic histories, produced by the Oregon State University Molluscan Broodstock Program (MBP), displayed markedly differential survival, yields, and growth rates during episodes of summer mortality at project study locations in California and Washington. There is a strong and consistent genetic response of families to environmental stress that is independent of when the families were produced and planted. In addition, prior inconsistent mortalities occurring across large culture plots can, at least in part, be explained by differential genetic backgrounds of the oyster crops. An ongoing western regional aquaculture center (WRAC) project is exploring an alternative approach of utilizing crossbreeding (crossing of inbred lines of oysters to produce "hybrids"). *C. gigas* heterosis ("hybrid vigor") indicates crossbreeding, in addition to traditional selection as practiced by the MBP, could improve growth and survival dramatically and quickly. Initial evaluations of hybrid lines grown out in Hood Canal, Washington in 2001 to 2002 suggest performance was exceptional.

Figure 1.

(2) Triploid and diploid oysters appear to have different optimal environments and definition of their respective requirements and response is essential for maximizing their survival and productivity. Field experiments and grower observations have demonstrated sporadic high triploid mortalities and wide variation in survival compared with diploid oysters planted at the same locations. Overall, triploid oysters grown at Puget Sound test sites in

2000 to 2002 experienced a cumulative mortality of 8%–28% above the mortality rates of diploid oysters planted in comparable plots. Tests are underway to measure the performance, survival and physiologic condition of selected strains of diploid and triploid oysters outplanted from the same parent stocks during the 2003 growing season.

ZOOSPORULATION OF PREZOOSPORANGIA DERIVED FROM IN VITRO CULTURED *PERKINSUS MARINUS* MERONTS CULTIVATED IN MEDIA SUPPLEMENTED WITH OYSTER LIPID EXTRACT. Fu-Lin E. Chu* and Eric D. Lund, Virginia Institute of Marine Science College of William and Mary Gloucester Point, VA 23062 chu@vims.edu

Four life stages of the oyster protozoan parasite, *Perkinsus marinus* have been identified and described. They include meront, prezoosporangium (hypnospores), zoosporangium, and biflagellated zoospore. Previously when tissue-associated meronts were incubated in fluid thioglycollate media (FTM) for 4-5 days, they developed to prezoosporangia, and zoosporulation (production of biflagellated zoospores) usually occurred after incubating FTM-cultured prezoosporangia in estuarine or sea water for few days. However, in contrast to what has been observed in the past, in recent years following the similar procedure, low incidence of zoosporulation without release of the zoospores has been observed in several laboratories. We hypothesize that deficiency of essential nutrients (e.g., lipids and essential fatty acids) in prezoosporangia is one of the causes of the problem. To test the hypothesis, we incubated *in vitro* cultured 21 day old meronts in alternative fluid thioglycollate media (AFTM) supplemented with oyster lipid extract and lipid-free AFTM. The concentration of lipid in the lipid-supplemented AFTM was comparable to that of oyster plasma (40 µg/ml). Prezoosporangia developed in lipid-supplemented AFTM and in non-lipid-supplement media were transferred to artificial sea water (ASW) and monitored for further development. The prezoosporangia cultured in lipid-free AFTM did not develop further. Within 24 h of transfer to ASW some prezoosporangia cultured in lipid-supplemented AFTM had developed discharge tubes. Development of cells was not synchronous, but some of the prezoosporangia exhibiting discharge tubes developed further to zoosporangia containing motile zoospores within 3 days of transfer to ASW. Free swimming zoospores were observed within 4 days of transfer to ASW. These results suggest that lipid and/or essential fatty acid storage in prezoosporangia is critical for their development to zoosporulation. Both FTM and AFTM contain limited amount of lipids and are deficient of the essential fatty acids such as arachidonic, eicosapentaenoic and docosahexaenoic acids. Presently we are determining the optimal amount of lipids required for prezoosporangia develop to zoosporulation and whether certain lipid classes or essential fatty acids are critical for such development.

DEVELOPMENT OF ANTISEPTIC PROCEDURE TO IMPROVE CULTURED PEARL FORMATION IN *PINCTADA MARGARITIFERA*. N. Cochenec-Laureau, P. Haffner, P. Levy, D. Sauthier, S. Langy, and A. Fougerouse,

Cultured black pearls from *Pinctada margaritifera* (Linnaeus) are a significant industry for French Polynesia. Pearl formation requires the inserted mantle tissue to form a complete sac around the shell nucleus and to secrete successive layers on nacre onto the bead.

Despite the relative success of this pearl formation method, substantial failures occurred. The purpose of this presentation is to study the effect of antiseptic process on mortalities from the surgery and nucleus rejection. The use of antiseptic during grafting experimentation had no significant effect on mortality and bead rejection. However, antiseptic has proven very effective in reducing the number of total bacteria isolated from pearl bag. Two dominant bacteria were isolated from *P. margaritifera* after nucleus insertion. Phenotypic and molecular characterization showed that one strain is similar to *Vibrio harveyi* and the other differs on one phenotypic character from *V. alginolitycus*. These results suggest that improvement of hygiene for all aspects of the pearl surgery really has great impact on reducing bacterial contamination. Further work is planned to confirm the possible impact of these two strains on mortality and/or nucleus rejection by experimental infection.

REVIEW ON AMINO ACID REQUIREMENT IN SHRIMP. G. Cuzon, J. Guillaume, and G Gaxiola, Ifremer, BP 7004, Taravao, Tahiti, French Polynesia. E-mail: gcuzon@ifremer.fr

Amino acids (aa) requirement in shrimp was rapidly assessed from a qualitative point of view, using ¹⁴C acetate. Lys-Arg-His, Leu-Ile-Val, Phe, Thr, Met, and Trp. However, knowledge on quantitative requirement was hampered by technical aspects, such as leaching from purified diets, differential of absorption at midgut level between crystalline aa, and aa derived from dietary protein digestion. Among species, *P. monodon* provided the largest amount of data (Millamena et al, 1996 to 1998) with quantitative values on basic aa, branched chained aa, Phe, Met, Trp, and Thr. It was obtained with experiments on juveniles raised in clear water at low density and constant water temperature; to some extent data on larvae and PL's were included.

TABLE 1.

Iaa requirement % of protein for *P. monodon* fed 40% CP during its main phase of development with rapid growth rate.

	LYS.	ARG	HIS	LEU	ILE	VAL	THR	PHE	MET	TRP
Juveniles	5.2	5.3	2.2	4.3	2.7	3.4	3.5	3.7	2.4	0.5

Protein and aa requirement were studied with reference protein (shrimp muscle, casein, squid, clam, etc), protein requirement expressed in terms of % (relative protein requirement) is probably not so highly correlated with protein accretion as it is in vertebrates due to chitin synthesis, polyholoside containing 43% equivalent raw protein, and among aa, Thr, His, Leu, or Ala.

Amino acid requirements were assessed with defined diets described in this paper, also imbalanced diets; oxidation method and indirect oxidation methods are reported. Values obtained were evaluated and compared among species. Whole body composition for a basis of EAA pattern appeared in good correspondence (Fig. 1).

Figure 1. Correlation between shrimp muscle and aa requirement of *P. monodon*.

Several authors faced problems with leaching or absorption at midgut-level when using amino acids diets. Experiments used the technique of everted sacs to express availability of aa.

WAS HAWAII, MARCH 2004: METABOLIC RATE OF *PINCTADA MARGARITIFERA* DURING GAMETOGENESIS. G. Cuzon, C. Soyez, and G. LeMoullac, Ifremer, COP/ BP 7004 Taravao, Tahiti French Polynesia

P. margaritifera, the mother pearl is cultured extensively in French Polynesia and research on environmental rearing conditions were conducted in Tahiti (Ifremer, Service de la Perliculture, and UFP) during a multi-disciplinary program named PGRN (1993 to 1999). It led to a comprehensive approach of trophic level in lagoon waters, feeding habits, and carrying capacity.

Research for the control of spat production in hatchery is conducted at Ifremer/COP/Tahiti. One of the preliminary steps consists in the maturation of the broodstock under laboratory conditions and the results presented here provide information on the nutrition and physiology aspects of the problem. Some tools (respirometer, analytical procedures) provide physiologic measurements (respiration, excretion) taken from animals maintained in the laboratory. Adults were placed in raceways with a flow

through system (0.5 m³/hour) and compared in two situations. Animals received unfiltered water lagoon or the same water plus a regular supply of algae (*Chaetoceros* or *T-iso* or *Pavlova*) at a concentration of 20,000 cells per ml for a period of 8 weeks at 27 °C.

Figure 1. Oxygen consumption recorded on adults placed in a microcosme for 20 hours and reflecting two different nutritional status (seston or seston + algae).

Oyster without additional food respired at a lower level (4 µmol O₂/jour/individual) than animals with a supplemental algae ration (14 µmol O₂/jour/individual). Additional measurement of ammonia excretion and a calculation of feed intake helped to produce a scheme of energy partition during the gametogenesis period, moreover it was possible to calculate an O:N ratio that differed between the two conditions of acclimation. Then, energetic substrate changed.

By and large, oysters received a net energy (NE) of 1.5kJ/oyster/day versus 5.0 kJ/oyster/day in a situation with additional food. Nutritional status for animals placed in raceway with a high renewal water and microalgae distributed daily is significantly improved. Animals with supplemental food produced higher indices of gametogenesis (gonadic indices) than the others.

A benefit through the supply of essential nutrients such as DHA, EPA, arachidonic acid, sterols, and phospholipids needed during this phase of gametogenesis is probably part of the explanation of the results from a nutritional point of view and need further analytical work.

PHYSIOLOGICAL ECOLOGY OF THE CULTURED HARD CLAM, *MERCENARIA MERCENARIA*. Elizabeth S. Darrow, Mark W. Luckenbach, and Roger Mann, Virginia Institute of Marine Science, College of William and Mary, Gloucester Point, VA 23062, USA. E-Mail: edarrow@vims.edu

Aquaculture of the hard clam, *Mercenaria mercenaria*, is one of the largest agricultural industries on the Eastern Shore of Virginia. Over the course of development of this industry in the region, marked improvements in clam growth rates were initially realized, as a result of better site selection, improved growing

techniques, selective breeding, or some combination of these factors. In recent years, some decline in clam growth rate has been reported by the industry and there is speculation that the carrying capacity of some grow-out areas has been exceeded. As part of a larger project to evaluate the limits on clam growth rates in this system, we developed an energy budget for these clams that have been selected for fast growth.

We hypothesized that aquacultured clams in Cherrystone Inlet, a tidal creek tributary of the Chesapeake Bay, would have different growth rates than wild clams, owing to changes in either (1) energy acquisition processes (ingestion rates) or (2) energy expenditures (metabolic, excretion, and egestion rates). Ingestion and egestion rates were determined using a flow-through system at *in situ* temperature and salinity, using natural seston from Cherrystone Inlet. After a 3-hour feeding trial, water samples were collected from each chamber's inflow and outflow tubes and analyzed for chlorophyll, cell counts, and total suspended solids. Ingestion rates were calculated by measuring the change in chlorophyll, particles, and particulate organic carbon (POC). Egestion rates were measured by collecting feces from each chamber and determining POC content. Assimilation and growth efficiencies were calculated for each individual. Metabolic rates were determined for the same temperature and salinity range by measuring oxygen depletion due to clam respiration in a gas-impermeable chamber using polarographic oxygen sensors. Simultaneously, excretion rates were calculated from the change in dissolved inorganic nitrogen (DIN) in the static system. All physiologic rates were measured for the full range of cultured clam sizes, from approximately 15 to 50 mm. Clam growth rates were measured on a monthly basis in the field for the same size range.

Results indicate that ingestion rates of cultured clams lie within expected ranges according to previously existing generalized hard clam and bivalve feeding models. This study also implicates a few potential sources of variation in clam ingestion rates, including seston (food) concentration and tidal cycle stage. These factors may be responsible for the observed bimodal distribution of ingestion rates among bivalves known as "high gear" and "low gear".

EVALUATING THE AQUACULTURE POTENTIAL OF ARCTIC SURFCLAMS (*MACTROMERIS POLYNOMA*) IN THE GULF OF MAINE. Christopher V. Davis and Sandra E. Shumway, Department of Marine Sciences, University of Connecticut, Goton, CT 06340.

The Arctic surf clam *Mactromeris polynoma* (Stimpson 1860), is a cold water circumboreal species distinguished from other surfclams by its purple foot, siphon, and mantle edge that turn brilliant orange-red upon being cooked. Increased demand for wild surfclams to supply the Japanese sushi market prompted a preliminary investigation of the aquaculture potential for cultivation of this species in Gulf of Maine waters. Studies were undertaken to determine the feasibility of rearing this species from biologic, technical, and commercial perspectives.

Hatchery-based studies to determine optimal rearing conditions documented early embryonic development, larval growth, and survival of replicate cohorts cultured under various environmental conditions. Laboratory and field grow-out studies investigated the effects of substrate type and growing site on juvenile growth and survival. A laboratory-based feeding experiment evaluated the uptake and release kinetics of surfclams when fed bloom concentrations of the toxic dinoflagellate (*Alexandrium tamarense*). Finally, a marketing study determined farmgate price, niche markets, and acceptability of fresh, farm-raised surfclams in the North American market sector. Results from these studies and the implications for aquaculture production are discussed.

EFFECT OF A DIETARY CONDITIONING USING LIPID EMULSION ON IMMUNE RESPONSE OF THE PACIFIC OYSTERS *CRASSOSTREA GIGAS*. Maryse Delaporte, Fu-Lin Chu, Chris Langdon, Eric Lund, Vincent Encomio, Georgeta Constantin, Philippe Soudant, and Jean-François Samain, Ifremer Brest Center, BP 70 29280 Plouzané, France. E-mail: Maryse.Delaporte@ifremer.fr

A preliminary study showed that dietary conditioning with three different algae of different fatty acid profiles affected the immune functions of the Pacific oysters *C. gigas* as well as the manila clams *R. philippinarum*. This suggests that a relationship between the essential polyunsaturated fatty acid (PUFA) profile of the diet and immune functions seems to exist in mollusks as in vertebrates. Nevertheless, the effect of individual PUFAs on the immune function cannot be clearly established. So we decided to test the effect of each PUFAs by using artificial diets, and we first tested the effect of 20:5(n-3) PUFA on the immune functions of oysters *C. gigas*.

To do this, oysters were fed either T-*Iso* alone or T-*Iso* supplemented with lipid emulsion during 1 month (mid-February to mid-March 2003). EPAX 4510 TG, an oil marine mixture of triglycerides rich in 20:5(n-3) (45%) and 22:6(n-3) (10%), was retained as the lipid emulsion. Different levels of emulsion were added continuously with the algae to the flow-through seawater: 0%, 1%, 10%, and 50% of the lipid emulsion. Moreover, at the end of the conditioning, 3 weeks of starvation were applied. During the experiment, different immune parameters were followed using a flow cytometer: hemocyte concentration, viability of cells, phagocytosis and the "oxidative burst" activity of hemocytes. At the same time, gills were removed from oysters that hemolymph were sampled for measurement of immune parameters to determine the effects of dietary conditioning on the lipid profile of gill membrane.

Preliminary results showed that the dietary conditioning was efficient: oysters maintained their condition index. However, the highest level of supplementation (50%) did not result in higher condition index than other treatments.

The dietary conditioning affected the immune system of oysters. Oysters fed 0% and 1% emulsion had similar hemocyte con-

centrations, whereas oysters fed 10% and 50% emulsion exhibited significantly higher hemocyte concentrations (Fig. 1). Results also revealed significant differences in phagocytic activities among treatments.

Figure 1. Haemocyte concentrations of oysters during the dietary experiment. Small letter indicate significant difference between dietary treatments (ANOVA, $p < 0.05$).

AUSTRALIAN SCALLOP SEABED CULTURE: FROM CONCEPT TO COMMERCIALIZATION. P. F. Duncan, S. Wang, E. O'Brien, W. Knibb, B. M. Degnan, and T. Wittingham, Faculty of Science, University of the Sunshine Coast, Maroochydore DC, Queensland 4558, Australia. E-mail: pduncan@usc.edu.au

The *Amusium balloti* fishery is one of Queensland's most valuable, but has varied in value between A\$15–24m/annum in the last decade. Although variability is common in scallop fisheries, the recent Queensland trend has been declining CPUE. Also, pressure to reduce environmental trawling impacts has changed fisheries management policy and resulted in a >30% fleet reduction. To maintain the economic and social benefits associated with the fishery, alternative production and management options are being considered with particular interest in aquaculture and ranching.

Wild spat collection and larviculture has been limited until recently, restricting aquaculture development, but advances in Queensland and Western Australia have enabled seabed culture projects in both states. The Queensland project is reviewed.

Since 1999, spawning, larval development, culture environment (eg, temperature and feed), larval settlement and attachment, and post-settlement behavior have been investigated. Spawning induction is via heat shock, early larval growth is highest at 20 °C, with survival highest at 18 °C. Larval survival and growth are better with multi-species algal diets, although Tahitian *Isochrysis galbana* (T-iso) alone gave good results. Artificial chemical cues increased larval settlement and metamorphosis, but substrate type had no effect. Biofilm exposure increased metamorphosis, but also mortality rates. Downwelling systems improved survival com-

pared with traditional settlement tanks and continuous aeration is essential. The larval cycle is about 25 days.

Current research is addressing the population genetics and taxonomic status of Western Australian and Queensland wild saucer scallop populations. Understanding the existing population structure is an essential component of a responsible marine release program. Previous allozyme work has indicated a probable taxonomic differentiation between west and east coast populations. Cytochrome oxidase and mtDNA markers will be applied to this question, which may have important implications for larval production, release and management strategies in the two programs.

A key component in project development has been the collaboration between industry and researchers. Queensland Sea Scallop Ltd. was formed in 2002 and has recently obtained the first seabed licenses for aquaculture in Queensland.

PROGRESS IN THE DEVELOPMENT OF EFFECTIVE PROBIOTIC BACTERIA FOR BIVALVE SHELLFISH HATCHERIES AND NURSERIES. Ralph Elston, Karen Humphrey, Arthur Gee, Daniel Cheney, and Jonathan Davis, AquaTechnics, PO Box 687, Carlsborg, WA 98324, USA. E-mail: aquatech@olympen.com

In small-scale laboratory systems we have tested the efficacy of multiple probiotic bacterial candidates to protect Pacific oyster (*Crassostrea gigas*) larvae and juveniles against challenge by bacterial pathogens and to increase survival of unchallenged hatchery-produced larval oysters. Studies focused on three promising bacterial strains isolated in the region of the shellfish production facilities. In well plates with 12 replicates, probiotic candidate P02-45 added at a concentration of 10^5 cfu per mL resulted $84.9\% \pm 4.8\%$ (1 SD) survival in larvae challenged with 10^4 cfu of a moderately pathogenic *Vibrio*, compared to $44.6\% \pm 4.2\%$ survival in challenged larvae without probiotic added. We repeated this experiment on additional spawn groups of larvae with similar results. We also found that addition of the probiotic candidate P02-45 added to unchallenged hatchery production batches of larvae could result in a survival improvement as great as from 21.0% without probiotic to 76.5% with probiotic when tested over 48 hours.

Tests are underway to scale up the test volumes and test the efficacy of killed bacteria. We also evaluated the compatibility of probiotic candidates P02-45 and P02-1 with seven species of algal food. We found that these probiotic candidates were compatible with some algal foods and even resulted in an increased density of food cells. Two algal species compatible with the probiotic candidates were Tahitian *Isochrysis* and *Rhodomonas* sp. (Fig. 1). Examination of the bacterial concentrations in these algal cultures showed that they reached a range of 10^5 – 10^6 cfu/mL, an effective concentration for providing probiotic protection. Addition of algal

cultures containing probiotic bacteria provided protection for larvae challenged with pathogenic *Vibrio* sp.

Figure 1.

We tested the highest concentration of probiotic that could be tolerated by oyster larvae and found it to be approximately 10^7 cfu/mL. Above this concentration, the larvae appeared to die from anoxia because of the high bacterial concentration. We also tested the primary probiotic candidates for pathogenicity to larval manila clams (*Venerupis philippinarum*) and larval geoduck clams (*Panope abrupta*) and found them to be non-pathogenic.

Research supported by grant project number 2002-00362 from the US Department of Agriculture, Cooperative State Research, Education, and Extension Service, Small Business Innovation Research program.

CHARACTERIZATION OF HEAT SHOCK PROTEIN EXPRESSION AND INDUCED THERMOTOLERANCE IN *P. marinus* PARASITIZED EASTERN OYSTERS: LAB AND FIELD STUDIES. Vincent G. Encomio*; Fu-Lin E. Chu. Virginia Institute of Marine Science College of William and Mary Gloucester Point, VA 23062 vge@vims.edu

Eastern oyster mortalities caused by *Perkinsus marinus* (Dermo) are likely exacerbated by thermal stress. Conversely, enhancing thermotolerance in oysters may improve tolerance to thermal stress and disease. Sublethal heat shock has been found to increase tolerance to subsequent lethal heat stress (induced thermotolerance) in oysters. Increased heat shock protein (hsp) expression has been associated with induced thermotolerance. Heat shock proteins are also believed to play a role in protecting organisms from pathogenic stress. The objectives of our research are to characterize the heat shock response in the eastern oyster and deter-

mine its role in mediating stresses due to high temperature and disease.

To examine the interaction between thermal stress and parasitism, oysters were challenged with *Perkinsus marinus* and maintained until infection levels reached a body burden of 10^4 cells/g wet weight. Oysters were then heat shocked for 1 h at 40°C. Gill tissues were sampled at 0, 2, and 7 days post heat shock and analyzed for total hsp70 levels. At day 7, oysters were subjected to a lethal temperature of 45°C for one hour and survival was monitored for one week after lethal heat stress. Survival in heat shocked oysters was significantly higher than non-heat shocked oysters ($P = 0.013$). Infection status did not significantly affect survival. Despite an apparent induced thermotolerance, gill hsp70 levels decreased significantly over time ($P = 0.003$), counter to expected results. Further analyses will be conducted to determine if variability in isoform expression accounts for these changes. Seasonal hsp70 levels are also being compared in field deployed disease resistant and susceptible oyster stocks. Preliminary results show

Figure 1. Percent survival of oysters after lethal heat stress. HS = heat shock; non-HS = non-heat shocked.

Figure 2. Total gill hsp70 levels after heat shock.

that there is little variation in total hsp70 among stocks. Seasonal and induced expression of hsp70 will be compared among these stocks to determine the role of hsps in stress and disease tolerance of disease resistant oysters.

PRIORITIZING REGIONAL RESEARCH INITIATIVES FOR THE CONSERVATION OF ARKANSAS' FRESHWATER MUSSELS. Jerry L. Farris, John L. Harris, Bill Posey, and Alan Christian, Arkansas State University, Department of Environmental Sciences, Box 847, State University, AR 72467, USA. E-mail: jlfarris@astate.edu

Since summarizing Arkansas' freshwater mussel surveys over the past 6 years, questions have been raised concerning how best to utilize the data in developing successful management strategies for this declining group of aquatic invertebrates. Projects targeting habitat requirements, life history assessments, and propagation support have drawn upon our mussel database. This database was developed for GIS application to offer insight for best management practices and decision-making when resource sustainability and environmental protection are prioritized. It seems that priorities continue to demand an efficient level of collaboration among researchers and managers to insure meaningful progress towards answering the diverse range of questions concerning conservation planning. A review of the synergism in these conservation objectives and outcomes offers insight into the importance of prioritization of resources.

Initial large-scale surveys to delimit aerial extent of commercial mussel beds have led to improved coordination on river navigation maintenance activities such that the United States Army Corps of Engineers preapproval for dredging and disposal has resulted in significant protection of mussel resources. This in turn has led to an expanded effort for educating and equipping managers for identifying areas to support restoration and recovery of species such as *Potamilius capax*. Awareness of this mussel's distributions has even accounted for field validations of prescribed buffer zones for eradication of the boll weevil in agricultural production.

Developmental objectives related to efficiently handling, transporting and holding captive species have elucidated the importance of suitable refugia and hatcheries in supporting long-term observational and manipulative studies. The success of those efforts has now furnished important life history information and propagation of four different listed species. Attention is currently shifting to species of *Lampsilis*, *Pleurobema*, *Fusconaia*, *Cyprogenia*, and *Quadrula* to resolve important relationships utilizing phylogenetic assessments. All of these efforts have benefited from the coordination and dissemination of information by the Arkansas Fresh-

water Mussel Initiative. Such workgroups are key to making informed decisions in the face of limited budgets and critical time frames.

INORGANIC ELEMENTS AND DISTRIBUTION OF EASTERN OYSTERS. William S. Fisher, US Environmental Protection Agency, Office of Research and Development, National Health and Environmental Effects Research Laboratory, Gulf Ecology Division, 1 Sabine Island Drive, Gulf Breeze, FL 32561, USA

For over a century we have marveled at the high concentrations of inorganic elements, particularly zinc and copper, in oysters. Many have suggested that accumulations were inadvertent because the concentrations were too high to serve any known physiologic function. Recent evidence, however, has led to a hypothesis that eastern oysters *Crassostrea virginica* depend on substantial quantities of inorganic elements to serve in antimicrobial defense and shell deposition. Integral to this hypothesis is the understanding that ameboid blood cells (amebocytes) and adult shells can actively concentrate inorganic elements thousands of times over ambient.

Amebocytes in the mucus and gut of oysters seem to concentrate zinc, copper, and possibly tin, iron, manganese, and other elements from food and the water column. Discounting shell concentrations, zinc and copper are retained almost exclusively (?90%) in the amebocytes. Sequestration in membrane-bound amebocyte granules prevents toxicity and may provide storage until the elements are released in a defensive capacity. Extracellular release of copper and zinc (via degranulation) has been demonstrated during repair of wounds; they may serve as antimicrobial agents and initiate extracellular clotting. High metal concentrations released within a small area would provide a potent cytotoxic action against either potential pathogens or food organisms. An intracellular release of metals may occur similarly during phagocytosis when granules (lysosomes) fuse with particle-laden phagosomes. Adult oyster shells also contain high concentrations of the same inorganic elements that are retained in the amebocytes. High shell concentrations support a hypothesis that release of the elements from amebocytes initiates precipitation within the matrix of the organic conchiolin, leading to shell calcification. Amebocyte involvement in shell repair and pearl formation has been demonstrated in other molluscan species.

If eastern oysters are, in fact, dependent on high concentrations of inorganic elements, then they must inhabit areas that provide a source. Oysters are marine animals, but the elements are derived from terrestrial sources. Hence, oysters must live in close proximity to land or to freshwater flows that transport the elements. Oyster distributions match this supposition: they exist close to land and venture into deeper waters only within zones of freshwater influence.

WAS/NSA/AFS TRIENNIAL MEETING HAWAII 2004: EAST MEETS WEST. Gef Flimlin, Rutgers Cooperative Extension.

For the first time, members of the well-established Pacific Coast Shellfish Growers Association and the newly formed East Coast Shellfish Growers Association meet to discuss issues of mutual interest. The program will consist of discussions about Federal permitting of shellfish culture, foreign interest in US shellfish markets, organic labeling of cultured shellfish, assessing successful agricultural or aquaculture organizations, tempering harvested clams, interstate or interregional shipping of shellfish seed, update on post harvest treatment of shellfish, using a marketing board to improve profits, and environmental impacts of shellfish aquaculture. The two groups also address topics on which they can collaborate, and where they are focusing their energies presently.

ECONOMIC FEASIBILITY OF SMALL-SCALE, COMMERCIAL CULTURE OF BLACK PEARLS IN RURAL COMMUNITIES IN THE CENTRAL PACIFIC. Quentin S. W. Fong, Fishery Industrial Technology Center/Marine Advisory Program, University of Alaska Fairbanks, 118 Trident Way, Kodiak, AK 99615, USA; Simon C. Ellis, Mid-Pacific Marine Consultants, P. O. Box 2031, Kolonia, Pohnpei FM 96941, Federated States of Micronesia; and Maria Haws, University of Hawaii at Hilo, 200 W. Kawili St., Hilo HI 96720.

Traditional revenue sources for island nations in the Central Pacific such as copra have diminished significantly. Further, many of the high valued natural resources such as wild groupers for the live fish markets and sharks for their fins for the Asian markets, particularly Hong Kong, are being exploited and over-harvested by foreign fleets, using foreign labor with little economic benefits to the local population. With the dwindling of such natural resources, aquaculture is being considered and implemented from high-school education level to industry level to supplement the economic viability of outer island communities throughout Central Pacific.

This work provides an analysis of the economic feasibility of one of many small-scale aquaculture operations being considered, black pearl oyster farms, as one type of supplemental economic activity for outer island communities in the Republic of Marshall Islands. Specifically, projections of financial performance of a small-scale 25,000 seeded pearl oyster farm using the Tahitian long-line method are being conducted. Estimates of initial capital investment and annual operating costs are being formulated; an annual cash flow and enterprise budget are being developed. Preliminary results show that initial capital investment is approximately \$203,030. Annual operating costs is about \$221,212.

Net returns over a 20-year farm horizon average is \$128, 223 per year, based on the most conservative price data from published

sources. Sensitivity analysis on profit due to the variability of market price, survival, and cost of seed and other inputs will be conducted and results presented.

EFFICACY AND DEPLETION DYNAMICS OF OXYTETRACYCLINE USED IN THE TREATMENT OF WITHERING SYNDROME IN CALIFORNIA ABALONE *HALIOTIS SPP.* Abbreviated title: EFFICACY AND DEPLETION OF OXYTETRACYCLINE IN ABALONE WITH WS. Carolyn S. Friedman, Thea T. Robbins, George Trevelyan, Ray Fields, Eric Rosenblum, James D. Moore and Ronald S. Tjeerdema, School of Aquatic and Fishery Sciences, University of Washington, 1122 NE Boat Street, Seattle, WA 98195, USA. E-mail: carolynf@u.washington.edu

Withering Syndrome (WS) is a lethal bacterial disease of wild and cultured abalone, *Haliotis* spp., along the west coast of North America. Therapeutic treatment of WS was assessed using oxytetracycline (OTC) by injection and *per os* administration. Survival of OTC-injected abalone was significantly higher than that of sham-treated animals ($P < 0.001$ and $P < 0.05$). Microscopic examination revealed that all the animals that died had advanced WS and that tissue damage was beyond the ability of the animals to repair in the treated group. Feeding rates of treated abalone were also significantly higher than for sham treated control animals ($P < 0.001$ for black abalone and $P < 0.0001$ for red abalone). Oral administration for 14 consecutive days also effectively controlled WS in pilot and production scale applications. The treatment caused significant and persistent long-term reductions in the intensity of RLP infection and in the degree of morphological changes in the digestive gland ($P < 0.001$, $P < 0.05$, respectively) in treated individuals. On a pilot scale, using a 14-day treatment, mortality dropped from 36% in the control groups to 5% in the treated populations ($P < 0.001$). On a commercial scale, a dry floating feed containing 2.6% active OTC was just as effective. Withering syndrome caused high (41%) losses in control production tanks, but treated tanks experienced only 9% mortality ($P < 0.001$). Treated tanks produced 56% more market-sized abalone than control tanks ($P < 0.001$) resulting in 70% greater biomass of market-sized abalone relative to control tanks ($P < 0.01$). Concentrations of OTC in individual abalone foot muscle were variable and peaked at over 40 ppm. Residues declined to < 2 ppm, the federal tolerance level, between 15 and 22 d post treatment. The digestive gland however, appears to concentrate OTC and residence times have exceeded 3 mo based on a preliminary examination with levels as high as ~ 20 –180 ppm. Based on these data, we designed a study to optimize the efficacy of the OTC treatment (for 10, 20, or 30 d) and characterized the depletion dynamics of treated red abalone up to 122 d post treatment.

SEASONAL AND TEMPORAL VARIABILITY IN TISSUE BIOCHEMISTRY OF SEVERAL FRESHWATER MUSSEL SPECIES. Catherine M. Gatenby, Julie Boyles, Danielle Kreeger, Deborah Raksany, and Richard Neves, United States Fish and Wildlife Service, White Sulphur Springs National Fish Hatchery, WSS, WV 24986, USA. E-mail: Catherine_Gatenby@fws.gov

Freshwater mussel populations are highly imperiled worldwide. In the United States, approximately 70% of native species are in serious decline because of chronic environmental degradation, toxic spills, and the invasion of the exotic zebra mussel (*Dreissena polymorpha*). All 70 endangered mussel species recovery plans call for propagation and reintroduction of populations to achieve recovery. Additionally, propagation technology is viewed as a recovery mitigation tool for mussels killed by toxic spills or other anthropogenic impacts. To support successful propagation, baseline information on the nutritional demands of wild freshwater mussels is needed in order to develop suitable diets and feeding regimes for maintaining mussels in captivity.

Our goal is to quantify variability in physiologic status of several species of mussels from varying drainages and from different subfamilies. Proximate tissue biochemistry (protein, lipid, carbohydrate, and ash) was monitored in healthy populations of mussels collected from rivers in the Atlantic and Ohio River drainages over a 3-year period. Biochemistry varied seasonally and temporally across the years of study. Biochemistry also differed between the subfamilies of mussels. The mean carbohydrate level (%DTW) of each species was similar; whereas, the relative protein and lipid levels differed between species. These results reflect the reproductive and seasonal conditioning behavior of these animals, and their responsiveness to environmental changes. Until further information becomes available on absolute nutritional requirements, we recommend the following dietary composition for captive freshwater mussel diets: ~5%–10% carbohydrate, ~20%–40% protein, ~30% lipid, and ash ~20%.

VARIATION IN GROWTH AND REPRODUCTION OF BAY SCALLOPS FROM SIX SUBPOPULATIONS FROM THE NORTHEAST GULF OF MEXICO. Stephen P. Geiger, Janessa Cobb, and William S. Arnold, Florida Marine Research Institute, 100 8th Ave. SE, St. Petersburg, FL, 33701, USA. E-mail: steve.geiger@fwc.state.fl.us

Bay scallops (*Argopecten irradians*) can be found over a large geographic range: from Nova Scotia to Columbia. At the northern end of its range, reproduction occurs during the warm summer months. In the mid-Atlantic states, reproduction occurs when waters warm during the spring. In Florida, reproduction is conventionally believed to occur as water temperatures decline in the fall. Growth will often be limited to one body compartment: either somatic or reproductive. Often, somatic tissue weight will decline during the peak of reproductive growth. We examined variation in both tissue and somatic growth over a small geographic range: six

subpopulations of bay scallop along Florida's west coast. Beginning in April of 2002, we collected sets of up to 30 scallops in each of six subpopulations: St. Joseph Bay, Lanark, St. Mark's River, Steinhatchee, Homosassa, and Anclote. The collections were conducted at least once per month, but were conducted more often when possible, and continued through September. We determined shell height, wet weight and dry weight of adductor muscle, gonad, and all other tissue (hereafter termed viscera) and the volume of each adductor muscle.

One population, Lanark, was generally larger in all morphologic measures except gonad weight. Otherwise, the southernmost population, Anclote, began the season largest. This fits a general pattern observed in annual measurements of shell height during our spring survey. All populations had an increased gonadosomatic index in September. However, the gonad never exceeded 10% of the total tissue weight in the Anclote population, whereas gonads exceeded 20% of the total tissue weight in St. Mark's and St. Joseph Bay. Growth as measured by changes in mean shell height of the population was also higher in the three populations, which started smallest (St. Mark's, Steinhatchee and St. Joseph Bay; 4-6 mm/month), than the others (2.4-2.6 mm/month Homosassa, Anclote, and Lanark).

A possible explanation for our findings is that growth in the populations of bay scallops found in Florida's panhandle region more closely resemble those found in true temperate climates. They exhibit short periods of rapid growth and distinct spawning events. Those populations along peninsular Florida maintain slower growth throughout the year, but have more protracted growth and spawning seasons. Evidence from studies of juvenile recruitment is presented to support this theory.

ABUNDANCE OF HARD CLAM LARVAE IN THE INDIAN RIVER LAGOON. Stephen P. Geiger and William S. Arnold, Florida Fish & Wildlife Conservation Commission, Marine Research Institute, 100 8th Ave. SE, St. Petersburg, FL 33701, USA; and Marc Friseler, Skidaway Institute of Oceanography, 10 Ocean Science Circle, Savannah, GA 31411, USA.

The Indian River Lagoon complex, located on Florida's east coast, is a 220-km long system of three connected water bodies (the Mosquito Lagoon, the Banana River, and the Indian River) with both limited freshwater input and limited tidal exchange with the Atlantic Ocean. A naturally low circulation is further restricted by a series of man-made causeways connecting the mainland with the barrier islands that create the lagoons. Hard clams have been harvested from the lagoon since pre-historic times. Two periods of peak harvest dominated the commercial fishery, one in the mid 1980s and a second in the early 1990s. During each period, the value of the annual harvest peaked near \$8,000,000 (~0.5 million bushels). Current annual harvest is around 50,000 pounds per year. One characteristic of the fishery is that these rare sets that produce commercially harvestable densities of clams occur in highly local-

ized areas: usually a single water body within the complex. We have hypothesized that because of the limited circulation, larval supply is severely limited, reducing the opportunity for good sets of new recruits, especially in areas where adult densities are low. Unfortunately, identification of bivalve larvae, even to the genus level, or monitoring recruitment of juveniles is tedious and difficult.

To test the hypothesis of limited larval supply, we have been measuring the abundance of hard clam larvae through the use of a genetic probe. The 18s rRNA targeted oligonucleotide probe is specific to *Mercenaria* spp. (the Indian River has *M. mercenaria*, *M. campechiensis*, and hybrids between the two species). Use of this probe allows semi-quantitative estimates of larvae in unsorted plankton samples. The procedure entails extracting the total nucleic acid pool from the sample, binding it to a charged membrane, and visualizing the species-specific probed RNA on film after labeling with radioisotopes (in clams) or chemiluminescent compounds (for example in scallops). In order to test the efficacy we compared the technique to direct counts of bivalve larvae from sub-samples and also to a series of standards from cultured clam larvae.

Results from six sampling efforts in the Indian River Lagoon during the years 1998 to 2003 show that larval hard clam abundance in the complex is generally less than 20 larvae per liter but can vary spatially and temporally. Within a single sample period, the range of larval density from all stations is typically less than one order of magnitude. Variation between sample periods show that larval density can range from times when no larvae are present to times when larvae were detected at more than 90% of the stations sampled. Total bivalve larvae reach levels of hundreds per liter. The genetic probe method suggests that hard clam larvae usually represent <10% of the bivalve larvae present.

This technique offers a means by which researchers and managers can monitor larval abundances in natural systems and can explore the questions of whether larval supply is limiting or whether other life stages are critical in maintaining populations.

ENVIRONMENTAL CONDITIONS AND EXPERIMENTAL INFECTION WITH *P. MARINUS* MODULATE CELLULAR DEFENSE MECHANISMS IN THE EASTERN OYSTER *CRASSOSTREA VIRGINICA*. Michael Goedken and Sylvain De Guise, Department of Pathobiology and Veterinary Science, University of Connecticut, 61 North Eagleville Road, U-89, Storrs, CT 06269, USA. E-mail: michael.goedken@uconn.edu

The fast growing oyster aquaculture industry is greatly hindered by *Perkinsus marinus* and *Haplosporidium nelsoni*, which can kill up to 80% of production. The relationship between parasites, oyster defense mechanisms and their environment is unclear.

Phagocytosis (using fluorescent beads) and apoptosis (using Annexin-V FITC) of Eastern Oyster (*Crassostrea virginica*) hemocyte subpopulations were quantified at the single cell level utilizing flow cytometry. The influence of salinity (428 mOsm or 1.006‰ vs. 1006 mOsm or 1.025‰) and temperature (11 °C vs. 25 °C) were evaluated experimentally. Forward and side scatter distinguished two populations of hemocytes (granulocytes and hyalinocytes) with previously demonstrated unique functional characteristics. Controlled environment and infection studies revealed significant immune function alterations. Phagocytosis in granulocytes, but not in hyalinocytes, was higher at low salinity (428 mOsm or salinity of approximately 1.009) than at high salinity (1006 mOsm or salinity of approximately 1.025) when the water temperature was 25 °C. Phagocytosis was not affected by salinity when the water temperature was 11 °C. Temperature had no effect on hemocyte phagocytosis at either salinity. Apoptosis in both granulocytes and hyalinocytes was higher at 11 °C than at 25 °C when the water salinity was low (428 mOsm). Temperature had no effect on hemocyte apoptosis when salinity was high (1006 mOsm). Salinity had no effect on hemocyte apoptosis at either water temperature. Apoptosis in both granulocytes and hyalinocytes was higher upon *in vitro* infection with *P. marinus* compared to uninfected control cells. We demonstrated experimentally that water salinity, water temperature, and experimental infection with *P. marinus* modulated oyster defense mechanisms. A better understanding of how these variables affect oysters' defense mechanisms may lead to management strategies that will result in reduced disease morbidity and mortality for oyster producers.

WORLD ABALONE FISHERIES AND AQUACULTURE UPDATE: SUPPLY AND MARKET DYNAMICS. H. Roy Gordon, Fishtech Inc., Box 6886, San Rafael, CA 94903, USA. E-mail: rgordon@fishtech.com and Peter A. Cook, Center of Excellence in National Resource Management, University of Western Australia, Albany, 6330, Australia.

Continued increases in cultured production, combined with an unfortunate proliferation in the illegal wild catch have resulted in a world abalone supply for the year 2002/2003 exceeding the historical abalone abundance of the mid 1970s. Sparked by the rising middle class in China, a global shift in abalone availability and distribution has occurred. These significant shifts demand inventive thinking on the supply side if prices are to remain at strong levels. Examples are given of approaches using new creativity in the world of abalone marketing, distribution, and processing.

FAO country by country abalone reporting for both wild caught and cultured abalone totals change significantly when further dissected and standardized. FAO practice of reporting totals for abalone shucked or not and the continuing practice of some countries still reporting their production by large groups of species, distorts

historical and current totals. The information that we present on worldwide legal and illegal wild catch and on cultured production has been adjusted to account for these anomalies.

AN EXPERIMENTAL TEST OF LARVAL SOURCE AND CULTCH TYPE ON CONSTRUCTED OYSTER (*CRASSOSTREA VIRGINICA*) REEF PERFORMANCE Jennifer Greene* and Ray Grizzle, Department of Zoology University of New Hampshire Durham, NH 03824 jenn.greene@unh.edu

The roles that the eastern oyster (*Crassostrea virginica*) plays economically and ecologically are of substantial importance in the Great Bay estuary (NH) where there has been dramatic declines in oyster abundances since the mid 1990s when the first MSX epizootic occurred. The study of oyster reef restoration techniques is a high priority goal in the New Hampshire Estuaries Project Management Plan. In accordance with this, the current research project was developed to test the following hypotheses: (1) Reefs constructed using disease-resistant spat perform better than reefs formed by native spat; and (2) Cultch material affects remote setting success and early reef performance. This research project also addresses the goals set for managing oyster populations both locally and Bay-wide but also with implications for other Northern estuaries with oyster populations. These hypotheses will be tested by constructing 12 randomly positioned mini-reefs adjacent to an existing oyster reef using a $2 \times 2 \times 3$ factorial design. Each mini-reef ($\sim 2 \times 3$ m) will consist of a combination of two experimental variables: larval source (Maine native and NY disease-resistant) and cultch type (concrete/granite and oyster shells). Each spat/cultch combination will be replicated three times. To provide information on spat set on live oysters, the existing reef at Adams Point will be sampled at the same intervals as the experimental reefs. The larvae were remotely set in July 2003 and reef construction is planned for October 2003.

Each group of larvae was set at Jackson Estuarine Laboratory individually (5,000,000 per set) by cultch type in two 3,000-gallon fiberglass tanks. Initial larval settlement densities for the native Maine broodstock on the concrete/granite cultch were 9.1% while the oyster shell had a higher settlement rate of 16.5%. Initial larval settlement for the NY disease-resistant larvae was 4.8% on the concrete/granite cultch and 1.6% on the oyster shells. After settlement, cultch bags were transferred to rafts anchored in an intertidal nursery area in a sheltered cove adjacent to the Laboratory. Growth and mortality will be measured on a weekly basis while in the nursery area. After transfer to reef area in early Fall, growth and mortality will be measured bi-monthly.

The overall goal of this research is to provide information useful for the design of an estuary-wide oyster reef restoration program. The State of New Hampshire has set a goal of restoring 20 acres of oyster bottom by 2010.

STRATEGIES FOR MAPPING DISEASE-RESISTANCE GENES IN THE EASTERN OYSTER, *CRASSOSTREA VIRGINICA* GMELIN. Ximing Guo, Ziniu Yu, Yongping Wang, and Susan Ford, Haskin Shellfish Research Laboratory, Institute of Marine and Coastal Sciences, Rutgers University, 6959 Miller Avenue, Port Norris, NJ 08349, USA. E-mail: xguo@hsrl.rutgers.edu

The eastern oyster, *Crassostrea virginica* Gmelin, faces two major diseases along much of the Atlantic coast: MSX (caused by *Haplosporidium nelsoni*) and Dermo (caused by *Perkinsus marinus*). Resistance to the two diseases has a genetic component and can be enhanced by selective breeding. The mapping of disease-resistance genes may improve selection efficiency through marker-assisted selection. Mapping disease-resistance genes in oysters faces three challenges: (1) the lack of several genetic markers; (2) the lack of well-defined inbred lines and the difficulty to differentiate susceptible from resistant phenotypes; and (3) inability to harvest their tissues. We have been testing the following strategies for mapping in the eastern oyster. For markers, we relied on amplified fragment length polymorphisms (AFLPs) because they are relatively easy to develop and use. We developed over 500 polymorphic AFLP markers and built a moderately dense linkage map. We constructed 15 reference families using Rutgers disease-resistant strains and oysters from Delaware Bay, Long Island Sound, and Gulf of Mexico to maximize the segregation of markers and disease-resistance genes. Three approaches are being used to identify and map disease-resistant genes. First, we are studying and comparing allele frequencies in selected and wild populations to identify markers that show consistent frequency differences. Secondly, we are screening for allele frequency shifts before and after disease-inflicted mortalities in families and populations. Finally, we are looking for concerted linkage of suspected markers on the genetic map. The use of large number of AFLP markers, multiple reference families, and several mapping approaches may lead to the identification and mapping of some disease-resistant loci in the eastern oyster.

PHYSICAL AND LINKAGE MAPPING IN THE EASTERN OYSTER *CRASSOSTREA VIRGINICA* GMELIN. Ximing Guo, Yongping Wang, and Ziniu Yu, Haskin Shellfish Research Laboratory, Institute of Marine and Coastal Sciences, Rutgers University, 6959 Miller Avenue, Port Norris, NJ 08349, USA. E-mail: xguo@hsrl.rutgers.edu

The eastern oyster, *Crassostrea virginica* Gmelin, supports major fishery and aquaculture industries in the United States. It is also a popular model species for molluscan research. The biology and ecology of the eastern oyster are relatively well understood, but our knowledge about its genome is rather limited. In an attempt to develop a basic genomic map for the eastern oyster, work has been conducted to develop tools for physical and linkage mapping. For

physical mapping, we have been using fluorescence in situ hybridization (FISH) for the cytogenetic characterization and mapping of oyster chromosomes. Many repetitive DNA sequences and genes have been assigned to oyster chromosomes by FISH, and some revealed interesting features of the oyster genome. The chromosomal location of rRNA genes, on the long arms of Chromosome 10 (10q) in all Pacific species and on the short arms of Chromosome 2 (2p) in all Atlantic species studied so far, provides an interesting divide between the Pacific and Atlantic species. Nine unique sequence probes (P1 clones) have been mapped to eight of the 10 oyster chromosomes, and more are being mapped. For linkage mapping, we focused on the development and use of amplified fragment length polymorphism (AFLP) markers. Over 500 polymorphic AFLP markers were developed, and a moderately dense linkage map was built. This preliminary map is being used for the mapping of disease-resistance genes in the eastern oyster. Microsatellite and Type I markers are being added to the linkage map. Segregation markers are being developed for the cytogenetically mapped P1 clones. The goal is to integrate the cytogenetic and linkage maps by assigning the same DNA sequences to specific chromosomes and linkage groups.

EVALUATION OF PHA ON DIATOM COLONIZATION AND GRAZING ABILITY OF RED ABALONE *HALIOTIS RUFESCENS* POSTLARVAE. María T. Gutiérrez-Wing, Carmen G. Paniagua-Chávez, and Ronald F. Malone, Institute for Ecological Infrastructure Engineering, Civil and Environmental Engineering Department, Louisiana State University, 100 CEBA Lane, Baton Rouge, LA 70803, USA.

Biodegradable plastics have been used in areas such as medicine and engineering. The use of these plastics in aquaculture could help greatly to resolve environmental problems or enhance the culture of different species. Polyhydroxyalkanoates (PHA) (Fig. 1) is a biodegradable biopolymer produced by bacterial fermentation of sugar.

The objectives of this work are to (1) evaluate the performance of PHA plates as a substrate for the colonization of diatoms used to feed red abalone post larvae and (2) determine the grazing ability of red abalone post larvae on diatoms attached to the PHA plates. For the first experiment, pieces of PHA (5-cm diameter) were placed separately in 500-mL flasks containing the diatom *Navicula inserta* or seawater. Growth and colonization of diatoms were registered every other day for 20 days. For the second experiment, red abalone post larvae were placed in 20-L buckets containing plates previously colonized with *N. inserta*. As control, plastic plates used commonly to grow post larvae in the hatcheries were used. Initial and final post larvae size and weight were registered to determine growth and body gain.

Figure 1. Scanning electron micrographs of PHA's.

QUALITY SURVEY FOR ALASKAN SHELLFISH IN THE UNITED STATES: IMPLICATIONS FOR MARKETING COOPERATIVE FORMATION. Erin Harrington and Quentin S. W. Fong, Fishery Industrial Technology Center/Marine Advisory Program, University of Alaska Fairbanks, 118 Trident Way, Kodiak, AK 99615, USA.

The volume of aquaculture shellfish produced in Alaska has increased more than 400% since the early 1990s. Increasing saturation of Alaskan shellfish markets has led the industry to look to markets outside the state. The intent of research is to determine shellfish buyers' relative preference various product characteristics of shellfish. Mail surveys and focus groups will be used to determine buyers' and market expectations for Alaskan cultured shellfish and to assess variables such as seasonality of consumption, destination of product, and preferred species and product forms. A conjoint analysis of buyers' preference is being conducted to deconstruct a buyer's overall evaluation of a product into its component attributes such as size, product form, price, and lipid content. Results will be paired with comparative analysis of attributes of shellfish produced in different regions of the state. Study results are intended to assist shellfish producers in gauging the feasibility of regional or statewide marketing cooperatives. Preliminary results will be presented.

A STAGE-BASED POPULATION MODEL FOR BAY SCALLOPS *ARGOPECTEN IRRADIANS* AND IMPLICATIONS FOR POPULATION-LEVEL EFFECTS OF HABITAT ALTERATION. Elizabeth K. Hinchey*, Mamita M. Chintala, and Timothy R. Gleason, U.S. Environmental Protection Agency, Atlantic Ecology Division 27 Tarzwell Dr. Narragansett, RI 02882 hinchey.elizabeth@epa.gov

Bay scallops (*Argopecten irradians*) inhabit shallow subtidal habitats along the Atlantic coast of the United States and require settlement substrates, such as submerged aquatic vegetation (SAV), for their early juvenile stages. The short lifespan of bay scallops (1-2 y) coupled with a dependency on an essential habitat (SAV) renders this species particularly vulnerable to coastal habitat alteration. We are investigating the effects of habitat alteration on bay scallop populations using a stage-based matrix population model, in which the life history of *A. irradians* is divided into five life stages (Fig. 1). By quantitatively representing the life history strategy of the bay scallop and directly incorporating stressor effects and stressor-response relationships for specific life stages

into model projections, the matrix model provides a framework for evaluating the risk that habitat alteration (in the form of decline in SAV habitat quality and quantity) poses to bay scallop populations. Model output relating the response of scallop population growth rate to environmental stressors will be presented, along with simulation results of the effects of habitat alteration on scallop populations. Through elasticity analysis, the model can also be used to evaluate management strategies for population enhancement and identify data gaps most critical to understanding the population dynamics of this economically valuable and dwindling species.

Figure 1. Life cycle representation of the stage-based population model for bay scallop (*Argopecten irradians*) with a weekly time step. G_i represents the probability of an individual surviving to the next stage class during a time step; P_i represents the probability of an individual surviving and remaining in that stage class during a time step; f_i represents the reproductive output of an individual in that stage class during a time step.

DIFFERENTIALLY EXPRESSED GENES IN RELATION TO SUMMER MORTALITY OF THE OYSTER *CRASSOSTREA GIGAS* REVEALED BY SUPPRESSION SUBTRACTIVE HYBRIDIZATION. Arnaud Huvet, Amaury Herpin, Jean-François Samain, and Charlie Cunningham, Laboratoire de Physiologie des Invertébrés, Ifremer, Centre de Brest, 29280 Plouzané, France, E-mail: ahuvet@ifremer.fr, and Sars International Centre for Molecular Marine Biology, Thormøhlensgt.55 N-5008 Bergen, Norway.

This project is part of the national multidisciplinary program "MOREST" recently begun in France with the aim of understanding the cause of summer mortality of juvenile *C. gigas*. Within this program, divergent selection criteria were applied at the Ifremer hatchery in La Tremblade (France). G2 progenies can be separated into two groups, R (for "Resistant") and S (for "Sensitive"), depending on their summer survival rates. Suppression subtractive hybridization (SSH) was conducted between R and S groups in order to identify the differential expression of key genes and dif-

ferences in physiologic function(s). Oysters from 3 R and 3 S groups were sampled during a mortality event in experimental conditions (summer temperature, reproductive period). Mortality in the 3 S groups was 80% whereas in the 3 R groups placed in the same tank it was less than 5%. The SSH library was generated using the Clontech PCR-select cDNA subtraction kit using mRNA from mantle-gonad tissues from a mix of 10 individuals from each R and S group.

Three hundred and seventy-six clones were obtained and screened on blots. One hundred and forty-eight clones (40%) appeared to be differentially expressed and were induced in the R group compared to the S group. These 148 clones were sequenced: 25% matched with the products of known genes; 6% matched hypothetical proteins; 9% displayed open reading frames of significant length but whose product was unknown and 40% appeared to be non coding sequences. Redundancy was approximately 20%. The SSH sequences that matched with known genes were clustered into 7 categories (Fig. 1).

Figure 1.

The SSH sequences that appeared as interesting candidates to investigate summer mortality were fully sequenced. Full-length cDNA were obtained for 8 clones. These transcripts encoded homologues of the following proteins: cavortin, a self-aggregating haemolymph protein; cyclophilin, accelerates the folding of proteins and is secreted in response to stress stimuli; isocitrate dehydrogenase, implicated in the cellular defense against singlet oxygen-induced oxidative damage; scavenger receptor, a cell surface protein recognizing microbial constituents on the hemocyte surface; precerebellin, a known immune acute phase protein; sodium glucose cotransporter; fatty acid binding protein; ATPase, H^+ transporting lysosomal protein, involved in ATP deg-

radation, acidification of intracellular compartments required for zymogen activation, receptor-mediated endocytosis.

For those mRNA, real time PCR analyses are in progress.

GROW-OUT FARM SKILL TRAINING FOR THE BLACKLIP PEARL OYSTER *PINCTADA MARGARITIFERA* IN POHNPEI, THE FEDERATED STATES OF MICRONESIA.

Masahiro Ito, College of Micronesia Land Grant Program, P.O. Box 1179 Kolonia, Pohnpei FM96941, The Federated States of Micronesia. E-mail: hiroito@mail.fm

As a part of a project called "Development of Pearl Aquaculture and Expertise in Micronesia" (the Project), the College of Micronesia Land Grant Program (COM) initiated a grow-out farm training program for the blacklip pearl oyster *Pinctada margaritifera* during the last quarter of 2001, using spat (juvenile pearl oysters) produced at the COM's pearl hatchery in Pohnpei, the Federated States of Micronesia. Because a major cultured black pearl farming occurs in the French Polynesia and Cook Island of the South Pacific, hatchery-based black pearl farming is yet to be seen in many countries except for a few countries like Australia, Indonesian, Japan, and Philippines. Grow-out technology for the hatchery-produced spat is now available in the Micronesian region, and the Project aimed at transferring pearl aquaculture technology immediately to Micronesia by developing local human resources for support and maintenance of the pearl industry once it is established. For this purpose, three demonstration grow-out farms were established for a skill training at two island communities in Pohnpei State: two at Parem Island with 16 (102 m in length) longline systems located one mile north from the hatchery; and one at Pakin Atoll with six longline systems located 20 miles west off Pohnpei main island. The training was not limited to the hands-on care of hatchery-produced spat, but also included all aspects of farm-related work, such as farming site selection, deployment and maintenance of longline system and farming equipment, wild oyster collection, preparation for pearl seeding (grafting), and post-grafting care. During the first phase of the project, the program focused on a "train-a-trainer" method and started with several locals from the island communities. Along with the progress of the Project's hatchery training and spat production, more trainees were recruited beyond the two island communities. The program has entered "the second generation training" by the first generation trainees since the last quarter of 2003. All the trainees were unemployed whose age ranged from youth to elderly locals and they were provided stipends according to their participation, skill level, and attitude toward work. More than 50 people have so far participated in this program. To exercise an important role in the regional extension and research and education programs, the project has already accepted several college and high school students for field studies and work-study programs. Elementary school children were also provided field excursions, and other local and overseas stakeholders such as business investors, diplomats, and sci-

entists visited the hatchery and the farms. This presentation describes the COM's skill training methodology of the ocean nursery culture and evaluates briefly its hatchery-based pearl farming technique.

HATCHERY TRAINING ON THE BLACKLIP PEARL OYSTER *PINCTADA MARGARITIFERA* IN POHNPEI, THE FEDERATED STATES OF MICRONESIA.

Masahiro Ito, College of Micronesia Land Grant Program, P.O. Box 1179 Kolonia, Pohnpei FM96941, The Federated States of Micronesia. E-mail: hiroito@mail.fm

A hatchery-based farming is considered to be the best option to develop a pearl industry in the Micronesian region where wild resource of blacklip pearl oyster *Pinctada margaritifera* is not abundant like countries in the South Pacific region. It is unfortunate, however, that only a handful of private companies in Australia, Japan, and Philippines have been successful in such a hatchery-based black pearl farming. Hatchery technology for this species has not readily been available in this region until recently (Ito et al. 1995, Ito et al. 1996, Lucas et al. 1995, Southgate and Beer 1997, Southgate and Ito 1998, and Southgate et al. 1998). The College of Micronesia Land Grant Program (COM) built a small low-tech hatchery at Nett Point, Pohnpei during the third quarter of 2001 to implement an intensive training program. Funding was provided by the United States Department of Agriculture (USDA) and Department of Interior's Office of Insular Affairs (DOI) in support of this search for the pearl technology under a project called: "Development of Pearl Aquaculture and Expertise in Micronesia" (the Project). Three Micronesian trainees were recruited, who neither had background in pearl industry nor aquaculture experience and higher education: former government office clerk, a former agriculture extension agent, and an unemployed from one of the outer islands in Yap State. The Project aimed to transfer pearl hatchery expertise immediately to the Micronesians and to create core technicians within a limited timeframe of 2 to 3 years of intensive hands-on skill training, which will become a vehicle for development of hatchery-based pearl farming in this region.

The Project has been proving its efficiency and accomplished its first phase objectives on hatchery training, involving 31 series of spawning trials and seven larval runs, during the phase 1: (1) handling of all aspects of hatchery-related skills, including equipment preparation and system maintenance, microalgae culture, spawning induction, larval rearing, and spat culture; (2) sampling and data collection on feeding, larval development, and spat growth for basic scientific studies; (3) spat production for commercial-scale demonstration farms; and (4) handling all aspects of grow-out culture of hatchery-produced spat. The Project provided the first step towards an alternative approach to establish pearl industry in Micronesia by transferring a hatchery-based farming technology. This presentation describes the COM's methodology on pearl hatchery training and to evaluate briefly such techniques

as spawning induction, larval rearing, and in-tank spat culture of the blacklip pearl oyster.

DEVELOPMENT OF PEARL AQUACULTURE AND EXPERTISE IN MICRONESIA. Masahiro Ito, Robert Jackson,

and Singeru Singeo. College of Micronesia Land Grant Program, P.O. Box 1179 Kolonia, Pohnpei FM96941, Federated States of Micronesia. E-mail: hiroito@mail.fm

Pearl industry in Micronesia has potential of becoming a major source of export income once it is developed. French Polynesia in the South Pacific alone exported over 100 million US dollars worth of cultured black pearls. Other Pacific countries are actively trying to develop their industry following the lead of French Polynesia and Cook Islands. Micronesian nations are far behind these South Pacific island nations in the development of production of its pearl industry. One of the reasons for this is the fact that there is not sufficient number of the blacklip pearl oysters that could be collected from the wild to supply pearl farms on a regular basis.

In 2001, the College of Micronesia (COM) embarked on a search for technology for production of pearl oyster spat in order to get around this lack of naturally occurring wild spat supply in Micronesian region. Funding was provided by the United States Department of Agriculture (USDA) and Department of Interior's Office of Insular Affairs (DOI) in support of this search for the pearl technology under a project called: "Development of Pearl Aquaculture and Expertise in Micronesia" (the Project). The general purposes of this project are to provide training programs for: (1) development of the pearl industry in Micronesia and (2) development of local human resources for supporting and maintaining the pearl industry once it is established. The funding support enabled the Project to commence its phase 1 activity during the first quarter 2001 and continued until the third quarter of 2003. All phase 1's objectives were accomplished: an Australian expert in pearl oyster hatchery technology was hired; a hatchery was established in an abandoned dock warehouse at Nett Point, Pohnpei; and the pearl expert and his Micronesian staff/trainees successfully conducted hatchery and ocean nursery events during the phase 1, resulting in tens of thousands of blacklip pearl oyster that are growing at the three demonstration farms, also established by the Project. Three Micronesian staff members are being trained as future trainers in spat production and farm grow-out technology, with participation of more than 50 trainees from local communities, schools, and colleges.

The Project entered phase 2 in the fourth quarter of 2003, proceeding to complete the necessary evaluations and demonstrations to the critical issues in the pearl industry development, including actual pearl production and business development. The phase 2 includes: (1) expansion of training of hatchery and grow-

out farm techniques, the second generation skill training by the Micronesian trainers; (2) implementation of pearl production trials and evaluation of seeding and pearl production techniques; and (3) collaboration with institutions in the region and government agencies in developing business models for the Micronesian pearl industry.

GROWTH AND SURVIVAL OF HATCHERY-PRODUCED SPAT OF THE BLACKLIP PEARL OYSTER *PINCTADA MARGARITIFERA* DURING THE OCEAN NURSERY CULTURE IN POHNPEI LAGOON, THE FEDERATED STATES OF MICRONESIA. Masahiro Ito, Martin Hagilmai, and Justino Smith,

College of Micronesia Land Grant Program, P.O. Box 1179, Kolonia Pohnpei, FM96941, The Federated States of Micronesia. E-mail: hiroito@mail.fm

Spat of the blacklip pearl oyster *Pinctada margaritifera* were produced from the hatchery built by the College of Micronesia Land Grant Program (COM) at Nett Point in Pohnpei, the Federated States of Micronesia. On Day 44 after fertilization, the spat attached to "in-tank spat collectors" were transferred to the grow-out farms, which were also built by COM. The growth and survivorship of the hatchery-produced spat were monitored during the ocean nursery culture. The spat were protected by spat bag (0.75 mm by 1.5-mm mesh) and suspended from a surface long line system at 2–3-m depth. After 2 months of initial ocean nursery culture, they were removed from the collectors and sorted into 48-pocket (4-mm square mesh) nets. At 4, 6, and 9 months of the culture, they were further sorted and transferred into 24-pocket (20-mm mesh) net, 15-pocket (30 mm mesh) net or lantern (9-mm mesh) net, respectively.

The spat grew to the mean (\pm SE) antero-posterior shell length (APL) and dorso-ventral shell height (DVH) of 38.0 (\pm 7.1) mm and 39.8 (\pm 6.4) mm, 57.4 (\pm 6.2) mm and 55.5 (\pm 7.1) mm, and 81.9 (\pm 8.1) mm and 83.9 (\pm 7.6) mm at 6 months ($n = 206$), 9 months ($n = 87$), and 12 months ($n = 118$) of the ocean nursery culture, respectively. The size of hatchery-produced spat after 184 days (6 months) of the ocean nursery culture in Pohnpei were similar to those at 196 days reported by Southgate and Beer (1997) from the northeastern Australia. Compared to the best growth in Australia given by Southgate and Beer (2000) for the hatchery-produced juveniles between 7 months (DVH 41.5 \pm 0.6 mm; $n = 40$) to 12 months (DVH 65.8 \pm 1.0 mm), those juveniles in Pohnpei grew faster from 6 to 12 months reaching to 83.9 \pm 7.6 with a maximum DVH recorded 97.6 mm. Survival rates from 4 to 12 months and 6 to 12 months in Pohnpei were 83.2% and 91.3%, respectively ($n = 6384$ at 4 months; $n = 5814$ at 6 months; and $n = 5310$ at 12 months). Ongoing hatchery and ocean nursery trials with several batches since the first quarter of 2002 revealed that the survival rates were constantly high during the monitoring periods from 4 to

6 months, 6 to 9 months, and 9 to 12 months, which scored between 88.9%–98.5%. Hatchery-produced juveniles also showed uniformity in their shape, example, average DVH/APL (\pm SE; n) ratios of the first and second batches from the hatchery runs in 2002 were 1.035 (\pm 0.050; $n = 118$) and 1.042 (\pm 0.085; $n = 139$) at 12 months of nursery culture, respectively, and there was no significant difference ($P > 0.05$) between their average ratios. These findings suggest that our grow-out culture methodology is proving its efficiency and the farming environment of the Pohapei lagoon in Micronesia is well suited for growing hatchery-produced *P. argaritifera*, and could have a potential for producing high quality black pearls also. Nuclei implantation commences from September 2003 to conduct pearl quality experiments using the hatchery-produced and wild-caught pearl oysters.

CAWTHRON'S ULTRA DENSITY LARVAL SYSTEM (CUDLS) FOR REARING LARVAE OF THE PACIFIC OYSTER *CRASSOSTREA GIGAS*. Achim Janke, Henry Kaspar, Nick King, and Sam Foster, Cawthron Institute, Private Bag 2, Nelson, New Zealand. E-mail: achim.janke@cawthron.org.nz

Conventional commercial systems for rearing bivalve larvae use large tanks with water exchanged every 2 to 3 days and larval densities of 5 to 10 larvae per mL at the start of larval rearing reducing to 1-eyed larva per mL just prior to settlement. Heating the large volume of seawater required for larval rearing incurs major capital and operating costs. Continuous exchange systems offer the potential to significantly reduce these costs.

All bivalve larval rearing systems require water exchange to prevent build up of metabolic wastes and subsequent degradation of water quality. In a static system, water quality is at its best immediately after water exchange and degrades progressively until the next water exchange. In a continuous system, water is exchanged constantly ensuring minimal fluctuation in water quality and allowing an increase in larval density. In CUDLS, the increase in larval density has resulted in water savings of up to 45% and a reduction in tank volume by 99% over the equivalent static system. Larvae have been reared for their first week at densities of over 1000 per mL without detrimental effects on growth or survival. Commercial production using this system has yielded over 35 million eyed larvae ($>350 \mu\text{m}$) after 18 days at 22 °C from two 170-L tanks with each tank exchanging seawater at 3.5 L per minute.

Larvae are fed mainly *Chaetoceros calcitrans* and *Isochrysis galbana* Tahitian strain (T-iso), with feeding rates determined by observation of larval condition and algal clearance rates. As a guide larvae are fed the equivalent of 80 *Isochrysis* cells per μL at the start of larval rearing and in excess of 200 *Isochrysis* equivalent cells per μL just prior to settlement.

SELECTIVE BREEDING OF THE PACIFIC OYSTER *CRASSOSTREA GIGAS* IN NEW ZEALAND. Achim Janke, Nick King, Rodney Roberts, and Henry Kaspar, Cawthron Institute, Private Bag 2, Nelson, New Zealand. E-mail: achim.janke@cawthron.org.nz

The Pacific oyster was accidentally introduced to New Zealand in 1971 and farming of this species now forms the basis of an industry worth 15 million USD per annum. Until recently, most oyster production in New Zealand was derived from wild caught spat. With the move toward single seed culture of hatchery produced spat, the opportunity exists for commercial growers to achieve genetic gain through selective breeding.

A Pacific oyster-breeding program was begun by the Cawthron Institute in 1999. The program uses randomly selected wild oysters as parents for the first generation of full-sib families, with recurrent selection both within and between families for subsequent generations.

A trial cohort of nine randomly mated full-sib oyster families was produced in 1999. After 5 months of grow-out significant differences ($P < 0.01$) in growth rate were found among families. After 10 months 95% of the oysters had reach marketable size. The fastest growing family was more than twice as heavy as the slowest growing family, and 25% heavier than the average. Significant differences in growth rate existed among the four grow-out sites ($P < 0.01$), but no interaction was identified between growth rate and site ($P > 0.05$) meaning that family rankings for growth rate were consistent across a range of culture methods and growing environments. Survival averaged 85% across the four sites. These preliminary results show that differences among families are significant and that considerable gains in growth rate can be achieved through selective breeding.

A second cohort of 60 full sib oyster families was produced in 2001. These oysters reached marketable condition in 2003 and work on assessing these families is underway. The best oysters from the top performing families in this cohort will be selected for use as parents of a second generation.

IMPACT OF THE REPRODUCTION DYNAMICS ON GENETIC VARIATION IN THE EUROPEAN FLAT OYSTER *OSTREA EDULIS*. Sylvie Lapègue, Nicolas Taxis, Delphine Lallias, François Bonhomme, and Pierre Boudry, IFREMER, Laboratoire de Génétique et Pathologie, Ronce Les Bains, 17390 La Tremblade, France. E-mail: slapegue@ifremer.fr

The European flat oyster (*Ostrea edulis* L.) is a marine bivalve whose natural geographical distribution ranges along the European Atlantic coast from Norway to Morocco, in addition to the Mediterranean and Black Sea. The latest results obtained on the genetic differentiation between these populations have led us to

pursue studies at a finer scale, in order to estimate the effective number of breeders and the temporal dynamics of reproduction and, more specially, recruitment. Several experiments were performed to document (1) the variance in allele frequencies during a natural settlement period; (2) the paternal contribution to fertilization by analyzing larvae sampled at the brooding stage within individual females; (3) the variance of individual reproductive success within an experimental population.

Firstly, 3 sets of collectors were successively deployed every 2 weeks and one set left during the whole recruitment period in 2001. In addition, adult oysters were sampled including 14 brooding females (ie, females presenting larvae in their paleal cavity). Their larvae were sampled and preserved in ethanol. Mitochondrial (12S fragment) and microsatellite (four loci) analyses were performed.

Although the temporal cohorts did not exhibit any differentiation on the basis of the microsatellite markers, a slight but significant differentiation was observed with the mitochondrial marker. Moreover, our data on the genetic variability of single-female progenies show that females can be fertilized by a highly variable number of males, which can be, in some cases, very low (Fig. 1). In such cases, a temporary low effective could lead to a level of inbreeding (even low) which would explain the correlation between growth and heterosis often observed.

Figure 1.

More investigations are needed to directly demonstrate that each male fertilizes several females. If males succeed in fertilizing several females, variability in environmental conditions should increase female variance in reproductive success more than male variance in reproductive success, thus reducing mitochondrial relative to nuclear effective size as has been observed in the study of the genetic structure of the populations along the species range.

COMPARISON OF FIVE REARING TECHNIQUES FOR THE GIANT SCALLOP *PLACOPECTEN MAGELLANICUS* IN THE GASPÉ BAY, QUEBEC, CANADA. Marie-Lyne Larrière, Laurent Girault, Fabrice Pernet, and Benoît Thomas, Centre collégial de transfert de technologie des pêches, 167 La Grande Allée Est, C.P. 220, Grande-Rivière, Québec, Canada G0C 1V0. E-mail: ml_larriere@globetrotter.net

The giant scallop is an indigenous species of the Gaspé Peninsula, which represents high commercial value; therefore it is potentially interesting. Several rearing techniques are available and it is preferable to determine which is the most adapted to the particular conditions of the Gaspé Bay before undertaking commercial culture.

Juveniles were therefore imported from Magdalene Islands in spring and autumn of 2001 in order to carry out this evaluation. They were immersed into the Gaspé Bay at three different depths into five kinds of devices: earrings (ER), pearl nets (PN), Wang-Joncas lanterns (WJ), Savoury cages (SC) and oyster tables (OT). Growth rates, mortalities and several environmental variables are being followed for each depth, each device and each season of transfer until 2004. Biochemical analyses will supplement field measurements.

Mortalities were high for the scallops transferred during spring, varying, according to device, from 59%–82% (Fig. 1). These losses are mainly ascribable to the combined stresses of transfer and spawning. Mortalities approached normal values after the autumnal transfer. Growth rates are comparable with those observed elsewhere in Quebec (Fig. 2). They are similar for ER, PN, and SC, but they are lower for OT and WJ. The effect of depth is more noticeable on the meat yield, which is higher near the surface, than on the shell growth rate.

Figure 1. Scallops cumulative mortality according to the rearing device.

Because Gaspé Bay presents significant interannual variations of the environmental parameters, the later follow-ups will be use-

Figure 2. Evolution of scallops average sizes according to the rearing device.

ful to determine the average and extreme conditions that consequently will optimize the rearing strategy. In addition, it is increasingly evident that the meat yield, which can only be determined at the end of the growth cycle, is the important factor in the determination of economic feasibility of each method.

POPULATION GENETICS OF THE BLACK-LIP PEARL OYSTER *PINCTADA MARGARITIFERA*. Teresa Lewis, Candace Martin, Cameron Muir, Maria Haws, Simon Ellis, Matang Ueanimatang, Donald David, and Manoj Nair, Hawaii Institute of Marine Biology, School of Ocean and Earth Sciences and Technology, University of Hawaii at Manoa, Kaneohe, Hawaii. E-mail: tdlewis@hawaii.edu

Pearl production is an important industry that promotes sustainable economic development and provides export income for various Pacific Island nations. Empirical evidence points towards a significant difference between pearls produced by different stocks of pearl oysters. For example, the island of Manihiki in the Cook Islands produces recognizably distinct pearls with unique coloration. Pearl buyers in French Polynesia noted that before large-scale pearl oyster transfers took place between the dozens of atolls in the Tuamotu Islands chain, atolls tended to produce pearls with recognizable differences in color, luster, and orient, critical factors in establishing price and a competitive niche. After massive stock transfers of spat between islands occurred, these island-specific differences disappeared. There is a need to develop sensitive, and accurate genetic fingerprints to facilitate monitoring and development of appropriate management practices in black-lip pearl oyster aquaculture. Hatchery operators require information to formulate strategies that will allow them to supply stakeholders with the requested spat while protecting biodiversity and the potential economic value related to genetic difference between

stocks. We are seeking to address this issue through the use of two DNA marker systems: amplified fragment length polymorphism and analysis of microsatellite DNA. Samples included in our analyses were collected from hatcheries in Hawaii, the Federated States of Micronesia, and the Republic of the Marshall Islands, and from natural stocks. Results from the combined outcomes of these two avenues of research will be presented.

EXPRESSION LIBRARY IMMUNIZATION FOR DEVELOPMENT OF VACCINES FOR USE IN AQUACULTURE. Teresa D. Lewis, Ichiro Misumi, Christopher D. Kelley, Michael L. Kent, and Jo-Ann C. Leong, Hawaii Institute of Marine Biology, School of Ocean and Earth Sciences and Technology, University of Hawaii at Manoa, Kaneohe HI, USA. E-mail: tdlewis@hawaii.edu

Various techniques have been applied for the development of vaccines against fish pathogens that impact aquaculture. For viruses, this has met with the most success by developing a vaccine against an immunogenic epitope in the viral coat glycoprotein. For bacteria, bacterins and sub-unit vaccines have been the most efficacious. Fish parasites generally have multiple life stages and the cellular immune response may contribute to a more successful protective response than the humoral response. Thus, development of vaccines against parasites has proven more problematic. Here we describe the technique of expression library immunization (ELI) and the application of this method for identifying immunogenic proteins of *Cryptocaryon irritans*. The usefulness of this method over other forms of DNA vaccination is its application against pathogens for which we have no *a priori* knowledge of the proteins encoded by the genome. An acquired protective immune response against this parasite has been observed in thick-lipped mullet, mummichog minnow, and barramundi that were immunized by controlled infections followed by challenge infection. Here we report on our progress in screening a *C. irritans* genomic expression library to identify immunogenic proteins suitable for use in vaccine development.

MARINE AGGREGATES AS RESERVOIRS FOR THRAUSTOCHYTRIDS SUCH AS THE BIVALVE PARASITE, QUAHOG PARASITE UNKNOWN (QPX). M. M. Lyons, J. E. Ward, Department of Marine Sciences, University of Connecticut, Avery Pt., CT, USA; K. R. Uhlinger, and R. Smolowitz, Marine Resource Center, Marine Biological Laboratory, Woods Hole, MA, USA.

Marine aggregates (eg, marine snow, organic detritus, and flocs) may enhance the transmission of shellfish diseases by at least two mechanisms: (1) as reservoirs, if aggregates concentrate

pathogens within their matrix; and (2) as vectors, if pathogen-laden, marine aggregates are more readily captured and retained by the gills of suspension-feeding bivalves. Northern hard clams (= quahog; *Mercenaria mercenaria*) from the northeast coast of North America have suffered severe mortalities from a bivalve parasite known as quahog parasite unknown (QPX). QPX is a facultative parasite but little is known regarding the ecology of QPX. Morphologic and molecular analyses have characterized it as a thraustochytrid. Thraustochytrids are single-celled, eukaryotic, fungal-like, marine protists associated with decaying vegetation, shells, and marine aggregates. The focus of this research is: if QPX is a thraustochytrid, and thraustochytrids are linked to marine aggregates then, are marine aggregates one of the reservoirs for QPX? Detection strategies for QPX-enriched marine aggregates, including fluorescent stains and *in situ* hybridization, will be presented along with endoscopic video illustrating hard clams filtering marine aggregates. Hard clams ingest some, but not all, aggregates. Those that are not ingested are collected at the base of the incumbent siphon until rejected as pseudofeces. Because this is also the site of QPX-filled nodules in infected clams from Massachusetts, we hypothesize marine aggregates facilitate infection.

POSTINGESTIVE SELECTION IN THE SEA SCALLOP *PLACOPECTEN MAGELLANICUS* ON THE BASIS OF PHYSICAL AND CHEMICAL PROPERTIES OF THE PARTICLES. Bruce A. MacDonald and Martha G. S. Brillant, Biology Department and Centre for Coastal Studies and Aquaculture, University of New Brunswick, Saint John, N.B. Canada E2L 4L5. E-mail: bmacdon@unbsj.ca

Suspension-feeding bivalves may enhance the energy value of their food supply by sorting particles before and after ingestion. Postingestive sorting in bivalves has been confirmed for several species, but few studies have attempted to isolate the factors influencing postingestive selection among different particles presented simultaneously. In a series of experiments sea scallops were exposed to (1) beads of different sizes and density to determine the importance of physical factors; (2) ^{14}C -labeled dinoflagellates and ^{51}Cr -labeled beads of similar size and protein-coated and uncoated beads of identical size but different colors; and (3) living and heat-killed *Chlorella* with different chemical composition to assess the influence of particle chemical characteristics. Comparisons of gut retention times demonstrated that *P. magellanicus* can distinguish between particles of different sizes and densities, retaining larger particles (20 μm) longer than smaller ones (5 μm) and lighter particles longer than denser ones. The ^{14}C : ^{51}Cr ratio in the stomach decreased over time, indicating that the scallops were sorting organic from inorganic particles. Flow cytometry studies showed that scallops retained protein-coated beads longer than uncoated beads indicating simultaneous postingestive selection based solely on chemical properties. *P. magellanicus* retained live *Chlorella* cells longer than nutritionally poorer heat-killed cells

demonstrating this species's ability to distinguish between two physically identical but nutritionally different forms of the same species of microalgae. These experiments have confirmed the ability of sea scallops to sort particles within the gut based on the physical and/or chemical properties. This capability will enable the sea scallop to efficiently process a diet that is extremely variable in quality and enhance the energy uptake while minimizing losses associated with digestion.

A COMPARISON OF DREDGE AND PATENT TONGS FOR ESTIMATION OF OYSTER POPULATIONS. Roger Mann, Melissa Southworth, and Juliana M. Harding, Virginia Institute of Marine Science, College of William and Mary, Gloucester Point, VA 23062, USA; and James Wesson, Virginia Marine Resources Commission, P.O. Box 756, Newport News, VA 23607, USA.

Exploited oyster stocks on public grounds in Virginia waters are subject to regular surveys effected using a traditional oyster dredge and, more recently, patent tongs. Dredges provide semi-quantitative data, have been used with consistency over extended periods (decades), and thus provide data on population trends. Patent tongs provide absolute quantification but are more labor intensive. Absolute quantification of dredge data is difficult in that dredges accumulate organisms as they move over the bottom, may not sample with constancy throughout a single dredge haul, and may fill before completion of the haul, thereby providing biased sampling. Selectivity of dredges versus patent tongs with respect to demographics has not been rigorously examined. The objective of this study is to compare data from both sampling protocols. Data for the study were taken from 1998 to 2001 surveys conducted in the James River, Virginia by the Virginia Institute of Marine Science and the Virginia Marine Resources Commission wherein the same stations were sampled by both techniques. Dredge surveys give data in oysters per bushel and assume no selective retention of live oysters with respect to shell substrate by the dredge. Data from patent tongs is archived as per tong estimates of oysters by size class and shell by volume. The hydraulically operated 1-m square tong used in VMRC/VIMS surveys is designed to sample on and below the reef surface, which includes elements of buried shell that are probably not well sampled by a dredge, although the sampling insures collection of all oysters within the tong mouth. Database entries were pooled with oysters <25 mm being distinguished as spat, the 25–75 mm being distinguished as sub market or small oysters, and >75 mm as market oysters, then bushel estimators applied as described earlier. This allowed estimation of both total volume and #/bushel, the unit given by dredge data.

The summary plot of mean values from 1998 to 2001 illustrates differences in the sampling gear. More shell per unit oyster (lower bushels counts) are found in a tong sample. The appropriate model for attempting to fit a predictive line is open to debate, and will be influenced by patent tong penetration as determined by the degree

Figure 1.

of consolidation of the underlying substrate. The data do not strongly support the ability to predict a relationship between dredge and patent tong population estimates at this time.

PERKINSUS MARINUS INFECTION RATES & PROGRESSION IN POPULATIONS OF SPECIFIC-PATHOGEN-FREE JUVENILE EASTERN OYSTERS *CRASSOSTREA VIRGINICA* PLANTED IN A TRIBUTARY OF CHESAPEAKE BAY. Carol B. McCollough, Christopher F. Dungan, Mark Homer, George R. Abbe, and Candace A. Morrellm, Maryland Department of Natural Resources, Cooperative Oxford Laboratory, Oxford, MD 21654, USA. E-mail: cmccollough@dnr.state.md.us

Specific-pathogen-free (SPF) oysters were set and reared in artificial seawater and transferred to four sites in the Patuxent River along a putative salinity gradient. Three sites were adjacent to natural oyster bars and one was remote from existing oyster populations. Deployments were made in September 2000, June and August 2001, and May and September 2002. Samples of 30 oysters were assayed at 2 and 4 weeks post-deployment for infection by *P. marinus* using an enhanced RFTM whole body burden technique. Assays continued at 4-week intervals until infections were detected in 3 consecutive samples, except the initial 2000 deployment was followed until 100% mortality occurred.

During drought conditions, SPF juvenile oysters acquired *P. marinus* infections as early as 2 weeks post-deployment. Infection rates declined markedly during freshet conditions (winter/spring 2003). SPF juvenile oysters placed at sites remote from natural oyster populations harboring *P. marinus* acquired infections at similar rates as SFP juveniles adjacent to natural populations. Both infection prevalences and mortalities demonstrated similar seasonal patterns.

EFFECTS OF MICROALGAL DIETS AND FATTY ACID COMPOSITION ON THE GROWTH PERFORMANCE OF POSTLARVAL AND JUVENILE BAY SCALLOPS *ARGOPECTEN IRRADIANS*. Lisa M. Milke, V. Monica Bricelj, and Christopher C. Parrish, National Research Council, Institute for Marine Biosciences, 1411 Oxford Street, Halifax, NS B3H 3Z1 Canada, and Department of Biology, Dalhousie University, Halifax, NS B3H 4J1 Canada. E-mail: lisa.milke@nrc.ca

Hatcheries often rely on multi-species algal diets for the production of postlarval and juvenile scallops, because nutritional requirements have not been adequately described. However, due to high costs of algal culture there is an incentive to reduce the number of species utilized. The goals of our study were: (1) to identify high-performance diets, comprised of a minimal number of species, that will maximize production of bay scallop postlarvae and juveniles and (2) to examine potential differences in the nutritional requirements, especially of lipids, at different developmental stages. To this end, postlarval (initial shell height, SH = 240 μ m) and juvenile (initial SH = 10 mm) bay scallops were offered 6–7 microalgal diet combinations at 20 °C, for 3 weeks.

Superior growth rates for both developmental stages were attained on a diet of *Pavlova sp.* (CCMP 459) and *C. muelleri* (CHGRA). This diet is characterized by elevated levels of n-6 fatty acids, arachidonic (AA) in CHGRA and docosapentenoic (DPA) in Pav 459, which may contribute to the high performance of this diet. In fact, the two diet treatments that were deficient in AA and DPA, *P. lutheri/T. weissflogii* and *P. lutheri/F. familiaica*, yielded the lowest growth rates at both developmental stages. These results, in conjunction with our previous work on sea scallop, *Placopecten magellanicus*, postlarvae suggests a dietary need for n-6 fatty acids across pectinid species.

The *T. striatal*/CHGRA combination, which is limited in docosahexaenoic acid (DHA), was the second highest performing diet in both stages of bay scallops although it is unsuitable for sea scallop postlarvae. Overall, limited enrichment of DHA was observed in the tissues relative to the diet, although there was a marked increase in tissue DHA/EPA ratios compared to the diets. This may be attributed to a decrease in EPA, possibly through selective catabolism and/or modification as has been previously suggested for *Argopecten purpuratus* larvae. This suggests that bay scallops may have less stringent dietary DHA requirements than sea scallops, and may be similar to oyster spat, *Crassostrea gigas*, which require either DHA or EPA, but not both, to sustain growth.

The *Rhodomonas lens*/CHGRA combination was the only diet exhibiting stage-specific differences in growth rate: it was a moderate diet for juveniles but poor for postlarvae. However, five of the six diets tested showed no difference in growth performance between stages, suggesting that in relation to growth performance, bay scallop postlarvae and juveniles have similar nutritional requirements.

DENSITY SEPARATION OF RECENTLY SETTLED MANILA CLAMS *TAPES PHILIPPINARUM* FROM THREE TYPES OF SEDIMENT. D. Munroe, D. Bright, and S. McKinley, Center for Aquaculture and the Environment, Faculty of Agricultural Sciences, University of British Columbia, 4160 Marine Dr., West Vancouver, BC, V7V 1N6. E-mail: dmmunroe@interchange.ubc.ca

Field studies are essential for the adequate study of larval biology and recruitment. Field study of the early juvenile life stages of wild intertidal clam populations is difficult because enumeration of bivalves in sediments is tedious and the accuracy is unknown. Therefore, a simple and effective method is needed to easily and accurately sample and count early juvenile bivalves from intertidal sediments. Here, we test the efficacy of methods for separation of recently settled Manila clams (*Tapes philippinarum*) from different types of intertidal sediments using density. Three aquaria were set up with sterilized sediments of each of the three sediment types: cobble/sand/shell, cobble/mud, mud/sand (9 tanks total), and each was filled with filtered, sterilized sea water heated to 20 °C and aerated. A known number of competent *T. philippinarum* larvae were added to each tank and allowed to settle and metamorphose, then the aquaria were drained and four sediment samples were taken from each aquarium for evaluation of number of juvenile clams present. Samples were wet sieved to isolate the size fraction from 125–500 µm, then this size fraction was settled through high density (1.9 g/mL) sucrose solution to separate stained clams from sediments. The average numbers of clams counted per sample for each sediment type were: 57.9 (SD = 37.1) for mud/sand, 60.0 (SD = 36.1) for cobble/sand/shell, and 53.1 (SD = 39.6) for cobble/mud (Fig. 1).

Figure 1. Means and 95% confidence limits for numbers of clams per sample for the three sediment types. The dashed line indicates the expected number of clams per sample (58.8) based on number of larvae placed in each tank. $N = 12$ for each treatment.

Based on the number of larvae originally added to each tank, the average number of clams expected per sample was 58.8 for all

three sediment types. There was no significant difference between the mean number of clams per sample and the expected value of 58.8 for all three sediment types. Therefore, these results indicate that the methods used here can be used to rapidly extract recently settled Manila clams from all sediment types with a high degree of accuracy.

STATUS OF BLACK LIP PEARL OYSTER FARMING IN THE REPUBLIC OF THE MARSHALL ISLANDS. Manoj R. Nair and Rand Dybdahl, College of the Marshall Islands, PO Box 1258, Majuro, MH96960, Republic of the Marshall Islands. E-mail: manojnair999@yahoo.com

Pearl farming is one of the important sources of revenue for several Pacific Island nations, including the Republic of the Marshall Islands (RMI). This aquaculture venture has been one of the main aquaculture revenue earners after the giant clam mariculture. The black lip pearl oyster *Pinctada margaritifera* is also available in some of the selected atolls of the RMI where they are being exploited for commercial purposes. There are 4 successful pearl farms in the country and they are in the process of expansion and several new entrepreneurs have also shown keen interest in pearl farming. However the major bottleneck for the successful and sustainable pearl farming in the region is the non-availability of sufficient wild pearl stocks. Earlier studies have shown that the natural stock in the RMI cannot support for the industry to go commercial in a sustainable manner and there is every possibility of the existing small stocks of pearl oysters being totally fished out. Experiments on wild spat collection in the different atolls have also given poor results. This problem has been overcome successfully recently with the development of commercial hatchery technology to produce spat for the industry. Seeing the importance and the potential of pearl farming as a primary or supplementary source of income to the community, the government is in the process of encouraging small-scale ventures as alternate income generation method to the traditional copra while simultaneously initiating steps on sustainable fisheries management strategies. The paper discusses the present status and the future pearl farming scenario in the RMI.

MUSSEL FARMING IN INDIA: PRESENT STATUS AND FUTURE PROSPECTS. R. Manoj Nair, USDA Land Grant, Cooperative Research and Extension, College of the Marshall Islands, PB-1258, Majuro, MH 96960, Republic of the Marshall Islands. E-mail: manojnair999@yahoo.com; K. K. Appukuttan, Molluscan Fisheries Division, Central Marine Fisheries Research Institute (CMFRI), PB-1603, Cochin 682014, Kerala, India; and T. S. Velayudhan, Molluscan Fisheries Division, Central Marine Fisheries Research Institute (CMFRI), PB-1603, Cochin 682014, Kerala, India.

India has two commercially important species of mussels, Green mussel *Perna viridis* and the Brown mussel *Perna indica*. In Indian literature green mussel was often described as *Mytilus viri-*

dis; this has been synonymized under *Perna viridis*. The former has a wide distribution along the Indian coasts and about 10,000 t of mussels are exploited yearly from the west coast of India, mainly from the state of Kerala. They support traditional sustenance fishing and scope of increasing natural production from existing beds is rather limited.

Mussel culture in India using *Perna viridis* and *Perna indica* was first conducted on an experimental scale in the early seventies by the Central Marine Fisheries Research Institute (CMFRI) at Calicut and Vizhinjam. Although the technology was developed by CMFRI in the mid and late seventies, it was only two decades later that the first commercial culture of mussels (Green mussel *Perna viridis*) was started (late 1995) at Anthakaramazhi (Alleppey District) in Kerala by local fishermen on long lines in the sea, with the technical support of CMFRI. Commercial mussel culture activity along the south west coast of India picked up in a big way since 1997 in different parts of Kerala in the open ocean and the estuaries lately by women groups, and Karnataka. Cultured mussel production is steadily increasing and it is expected to be about 1000 t in the year 2003; the production is projected to be 120,000 t by the year 2007 to 2008. Since the first experiments in the 1970s several new innovations have been tried. This paper discusses the evolution of mussel culture in India its development, present status, and its future prospects.

AN OVERVIEW OF PEARL FARMING IN INDIA. Manoj R. Nair, USDA Land Grant, Cooperative Research and Extension, College of the Marshall Islands, PB-1258, Majuro, MH 96960, Republic of the Marshall Islands. E-mail: manojnair999@yahoo.com; K. K. Appukuttan and T. S. Velayudhan, Molluscan Fisheries Division, Central Marine Fisheries Research Institute (CMFRI), PB-1603, Cochin 682014, Kerala, India.

India is well known for the production of beautiful natural pearls. India has a wealth of pearl producing oysters. The main ones among these are the Akoya oyster *Pinctada fucata* distributed from the famous Gulf of Mannar, Palk Bay, and Gulf of Kutch (mistakenly identified and wrongly reported by many even now as *Pinctada radiata*) and the Black lip pearl oyster *Pinctada margaritifera* in the Andaman and Nicobar Islands. Pearl culture in India was first conducted on an experimental scale in the early 1970s by the Central Marine Fisheries Research Institute (CMFRI) at its Tuticorin research center on the south eastern Coast of India. The institute had initiated experimental pearl production in 1972 and the first Indian cultured pearl produced the following year. Hatchery technology was developed by CMFRI for *P. fucata* and *P. margaritifera* in the early (1982) and late eighties (1987) respectively. With the technology, being standardized after repeated experimentation, sea farming of pearl oysters, cultured pearl production, hatchery production, etc was taken by private entrepreneurs and coastal community groups on both coasts of India pearl farm-

ing. This paper, in addition to giving an overview of evolution of the Indian marine pearl farming, also discusses the recent innovations like onshore pearl culture.

RECOVERY OF ENDANGERED MUSSEL POPULATIONS IN RIVERS OF THE EASTERN UNITED STATES. Richard J. Neves, Virginia Cooperative Fish and Wildlife Research Unit, US Geological Survey, 106 Cheatham Hall, Virginia Tech, Blacksburg, VA 24061, USA. E-mail: mussel@vt.edu

Of the nearly 300 species of native freshwater mussels in the United States, 35 are presumed extinct and 70 are federally listed as endangered or threatened. Because large mussels are capable of filtering roughly 40 L of water per day, historic mussel beds provided an ecologically important biofiltration function for most rivers in the central and eastern United States. Their filtration of phytoplankton, bacteria, and particulate organic matter from the water column provided an ecological service; namely, to enhance nutrient cycling and improve water quality for other species. The Freshwater Mollusk Conservation Center at Virginia Tech is now propagating and releasing endangered juvenile mussels of species in need of recovery. Initial releases of cultured juveniles began in 1997 and, since that time, roughly 100,000 endangered juveniles per year have been released into various river systems. The techniques and recirculating aquaculture technology now in use with rare species can be applied to any species in any river system of the country. Involvement in mussel propagation by state and federal facilities is now expanding to address the conservation needs of rare species and to produce juvenile mussels for toxicity testing, in order to assess whether water quality criteria are protective of these species. The restoration or augmentation of mussel populations in rivers provides another opportunity to improve water quality and sustain the health of freshwater ecosystems affected by anthropogenic stressors. Propagation of native freshwater mussels now provides a means to recolonize historic habitats and restore the natural biofiltration system of waterways throughout the United States.

BALLAN WRASSE *LABRUS BERGYLTA* PREDATION ON SCALLOP SPAT *PECTEN MAXIMUS*. G. G. Oppegård, T. Strohmeier, G. Bakke, O. Strand, I. Mayer, and A. Breistol, Department of Fisheries and Marine Biology, University of Bergen, High Technology Center, N5020 Bergen, Norway. E-mail: guri.oppegard@student.uib.no

Sea ranching of the great scallop (*Pecten maximus*) has been identified as having a high potential for future aquaculture in Norway. Until recently the edible crab (*Cancer pagurus*) and starfish (*Asterias rubens*) has been the major predators, causing great losses of released scallops. In order to reduce these losses a functional fence was designed to protect scallop sea ranches. The fence has improved the survival rate greatly.

The scallops are hatchery-reared and sold on to farmers at a size of 15–20 mm for on-growing. For protection against predation, the spat are grown in cages for the first 1–2 years before being seeded out onto the bottom. During this intermediate cage cultivation, the spat attain a size of 50 mm.

To reduce costs and avoid labor intensive cleaning associated with the intermediate culture, farmers are now seeding smaller spat into the fenced sea ranches.

During the summer of 2002 Helland Skjell AS, Norway, performed preliminary studies where spat (30–40 mm) were seeded from intermediate culture to bottom culture in a fenced site. Ballan wrasse (*Labrus bergylta*) were attracted to the area and the fish were observed to nab and eat on the spat. Studies on food preference for ballan wrasse performed in Ireland and France show various foraged species in stomach content where two other bivalves, mussel (*Mytilus edulis*) and *Chlamys* spp. are important prey.

The objective of this study is to find the maximum scallop size that the ballan wrasse can eat. This will provide information on the minimum spat size that can be released into fenced seabed avoiding heavy predation from ballan wrasse.

In experimental tanks (1 m³) the wrasse is given scallops in a size range of 15–35 mm, and foraged scallops are calculated after 1 week. Preliminary results indicate that the ballan wrasse do not eat scallop larger than 30 mm.

The first experiment is performed without bottom sediment. These results are compared with an identical experiment including sediment. A third aim for the study is to determine whether there are differences in survival success when the scallops are given time to recess in sediment before ballan wrasse is introduced into the tank, compared with a situation where spat are seeded in a tank with wrasse already present.

Results from these experiments will be presented.

ADVANCES IN THE CRYOPRESERVATION OF SPERM OF THE RED ABALONE *HALIOTIS RUFESCENS*. Carmen G. Paniagua-Chávez, Liliana Salinas-Flores, Miguel A. del Río-Portilla, and Rebeca Vásquez-Yeomans, Department of Aquaculture and Marine Biotechnology, Centro de Investigación Científica y Educación Superior de Ensenada, Ensenada, Baja California, México. E-mail: cpaniagu@cicese.mx

The demand for abalone throughout the world has increased dramatically and thus interest in cultivation has augmented. The culture of abalone in Baja California, México is a flourishing industry that requires supporting technologies. The cryopreservation of sperm of different species of abalone could be a good alternative, not only to solve conservation problems for endangered species, but also to improve the production of commercially reared cultures.

In previous years, different studies related to the cryopreservation of sperm of red abalone have been performed to optimize

protocols. Refrigerated storage (4 °C) of sperm and the effect of addition of antibiotics such as ampicillin, gentamicin, and antibiotic/antimycotic on the viability of sperm were evaluated. The use of antibiotics prolonged refrigerated storage of sperm and no significant differences were found on sperm motility after addition of antibiotics (Fig. 1). Moreover, bacteria growth was inhibited up to 90%. These results showed that refrigerated storage of red abalone sperm could be a helpful tool on hatchery management.

Figure 1. Left panel, trochophore larvae produced from thawed sperm. Right panel, thawed sperm stained with SYBR 14, propidium iodide and acridine orange.

Also, protocols to cryopreserve abalone sperm were designed. Acute toxic effect of cryoprotectants was determined by suspending samples of fresh abalone sperm in dimethyl sulfoxide (DMSO), propylene glycol (PG) or glycerol (Gly) at concentrations of 5%, 10%, 15%, and 20% for 5, 10, 15, 20, 25, and 30 min. The highest motility was observed in samples suspended for 5 min in 5% DMSO ($88 \pm 0.58\%$). However, no significant differences were found for sperm suspended in 5% and 10% DMSO or Gly and incubated for 5 and 10 min. Cryopreservation of sperm was held in three different freezing chambers: (1) Styrofoam box; (2) programmable rate freezing chamber (for clinical use); and (3) commercial freezing chamber (for bull sperm). The highest fertilization rate was found in samples frozen with 10% Gly in the commercial freezing chamber ($29 \pm 10\%$) (Fig 19). In addition, studies that could help to determine morphologic and ultrastructural changes produced by cryopreservation damage were performed. Membrane integrity after thawing was evaluated with the help of fluorescent dyes. The dyes SYBR 14 (100 nM) and propidium iodide (24 μ M) were used to assess membrane damage and acridine orange (38 nM) to evaluate acrosome damage (Fig 16). Also, The comet assay was used to determine DNA fragmentation. Additionally, larvae produced from thawed sperm were screened to determine chromosome abnormalities.

EFFECTS OF REMOVAL OF PUERULI FOR AQUACULTURE ON WILD CAPTURE SPINY LOBSTER FISHERIES. Bruce Phillips and Roy Melville Smith, Curtin University of Technology, GPO Box U1987, Perth, Western Australia 68445. E-mail: b.phillips@curtin.edu.au

What affect would the harvesting of pueruli have on the wild capture fishery for the western rock lobster, *Panulirus cygnus*? The managers and industry stakeholders in the western rock lobster

fishery are committed to maintaining "biological neutrality" harvesting limits, where biological neutrality is the level of catch that would need to be forgone to maintain the reproductive capacity of the breeding stock, if pueruli are removed.

Studies have shown that natural mortality of pueruli is high. Only few western rock lobsters survive from the time of settlement as pueruli (1 year old) until they recruit into the fishery, between 3 and 5 years later. Because of this high natural mortality, the impact of possible pueruli removals for aquaculture on subsequent catches is estimated on average to be minimal (Table 3), except in the case of removal of very large quantities of pueruli, and it is not the expectation that such large numbers will ever be removed.

TABLE 3.

Estimates of the number of lobsters remaining after harvesting different quantities of pueruli in the northern region of the fishery.

Number of pueruli at settlement (millions) in an average year	Number of lobsters at the beginning of fishing (millions)		Number of lobsters at the beginning of fishing (millions) for different numbers of pueruli removed
	without pueruli removals	Removal of pueruli (millions) for aquaculture	
600	9.55	5	9.53
		10	9.52
		20	9.49
		40	9.43

It would be possible to counter these small losses to the wild fishery, by effort reductions. For example, if it were decided to harvest 20 million pueruli from a 55 km stretch of coast in a high density settlement area, in an average puerulus settlement year, then approximately 1% of the pots in the pueruli harvesting area would need to be removed to maintain the size of the breeding stock. This converts to about 23,000 pot lifts or about 100 pots (an approximately 22 t reduction in catch) for the season.

WESTERN ROCK LOBSTER: POTENTIAL FOR ENHANCEMENT AND AQUACULTURE. Bruce Phillips, Roy Melville Smith, and Greg B. Maguire, Curtin University of Technology, GPO Box U1987, Perth, Western Australia 68445. E-mail: b.phillips@curtin.edu.au

The Fisheries Research and Development Corporation of Australia through the Rock Lobster Enhancement and Aquaculture Subprogram has funded three projects exploring the potential for enhancing the western rock lobster wild fishery catch and developing an aquaculture industry. The first project dealt with (1) the development of techniques to harvest large quantities of pueruli and (2) ensuring that any harvesting of pueruli was biologically neutral in terms of its effect on the wild capture fishery. The key research outcome of this project was that removing pueruli will

have a very minimal effect on catches in the wild fishery—and if necessary these effects can be compensated for. Findings from this project have led to two subsequent projects, which are now in progress. One has utilized the finding of high mortality rates in the first year after settlement, to explore the possibilities for enhancing catches in the wild fishery. This may be possible by improving the survival of pueruli and early post-pueruli by designing appropriate shelters for these juvenile animals. Another will be assessing the potential for on-growing lobsters by evaluating the growth rates and survival of pueruli to market sized lobsters, with and without refuges and at different densities. The biological data from this latter project will assist Industry investors in assessing the economic potential for western rock lobster aquaculture. Because Western Australia's immediate opportunity for rock lobster aquaculture is on-growing of pueruli, the longer-term prospect of completing the life cycle and producing pueruli from eggs has also progressed over the last 4 years.

EFFECTS OF REEF COMPLEXITY ON HABITAT FUNCTION FOR INTERTIDAL OYSTERS. Martin H. Posey, Troy D. Alphin, Heather D. Harwell, and Thomas Molesky, Center for Marine Science, UNC-Wilmington, 5600 Marvin K. Moss Lane, Wilmington, NC 28409, USA. E-mail: poseym@uncw.edu

Oyster reefs are increasingly recognized for their habitat and ecosystem functions. Oyster reefs provide forage and refuge habitat for fauna, affect local nutrient dynamics, impact water column particulates, and indirectly influence adjacent sandflat habitats. With the decline of oyster reefs along the Atlantic and Gulf coasts, efforts are increasing to conserve existing oyster areas and to restore lost oyster habitat. However, these efforts have often been based on a presence/absence approach without consideration of landscape aspects that may influence oyster health and ecosystem function. Location of oyster reefs relative to other habitats, size of reefs, oyster density, fragmentation, and reef architecture may all influence faunal use and other ecosystem functions. For intertidal reefs, vertical complexity and edge convolution are important landscape aspects influencing habitat quality. Vertical complexity refers to the 3-dimensional roughness of the reef, with greater complexity providing more diverse spatial structure and refugia. Because the reef edge is the point of initial contact for water flow and nekton on a flood tide, varying edge characteristics may affect flow around the reef and nekton use of boundary areas. Over the past 2 years, we have examined the influence of edge complexity, vertical complexity and reef fragmentation on faunal use of intertidal reefs, oyster recruitment, growth and survival, and the influence of these parameters on the adjacent sandflat community.

Interactive and main effects of vertical complexity, edge convolution and reef fragmentation were examined using created reefs providing replicate sets of each treatment (Fig. 1) as well as sampling of natural reefs with varying surface complexity and fragmentation.

Figure 1. Artificial reef treatments: A: low surface and low edge complexity, B: low surface complexity and high edge complexity, C: high surface complexity and low edge complexity, D: high surface and high edge complexity.

Results to date indicate that the various biotic components respond differentially to aspects of reef architecture. Epifauna, especially xanthid crabs, are more abundant on high surface complexity reefs. Oyster recruitment and initial survival is greatest on low surface complexity reefs, possibly representing an indirect influence of xanthid distributions. Nekton respond more strongly to reef fragmentation than either surface or edge complexity, with greater diversity and abundances of certain taxa on fragmented reef complexes. In contrast, connections between reefs and adjacent sandflat habitats, including influences on organic content, porewater N, sediment characteristics, and microalgal biomass, are affected more by reef edge characteristics than vertical complexity. These results indicate the potential importance of landscape factors for reef habitat function and indicate the necessity of considering reef characteristics in restoration and conservation efforts.

STEROID INDUCED ENHANCED OVARIAN MATURATION IN THE GULF COAST OYSTER *CRASSOSTREA VIRGINICA*. Roberto Quintanna, John Supan, and John Lynn, Louisiana State University, Baton Rouge, LA 70803, USA. E-mail: rquintl@lsu.edu

Oogenesis is a complex sequence of events endowing the ova with the cell machinery and nutrients (vitellogenins) necessary to respond to spawning cues and sperm interaction. Although invertebrate animals are not as well documented, there are emerging patterns of peptide and steroid hormones in reproductive cycles, which are similar to those in vertebrate animals. Experiments to assay the response of *C. virginica* to low level doses of estradiol-17 β (E_{17}) were performed in August and September 2001, the end of the normal maturation and spawning season of this species on the Gulf coast. Treatments were calculated based on the earlier reports of E_{17} concentrations in *C. Gigas* and calculated for body tissue mass of the whole animal estimated from shell length. Experiments ran for 14 days with a single E_{17} dose injected into the abductor muscle. Evaluation of E_{17} treatment was based on visual assessment of gonadal condition, the response of the excised whole animal to a solution of 0.01 mM 5-hydroxytryptamine (5-HT)

during a 45 min treatment period (Table 1), and histologic examination of samples taken at the gill-palp junction post 5-HT.

More females released oocytes in response to 5-HT following E_{17} treatments than the controls ($P < 0.001$, pooled data) (Table 2).

TABLE 1.

Experiment date	Dosage ng/gm wet weight	5-HT response # (%)	Total animals
8/18/01 controls		2 (20%)	8
8/18/01 estradiol		8 (58%)	14
9/15/01 controls		6 (35%)	17
9/15/01 estradiol		8 (40%)	20
9/22/01 controls		2 (13%)	30
9/22/01 estradiol		11 (35%)	32

Qualitatively, the development of gonadal tissues in treated animals was visually enhanced compared to the controls. Animals receiving lower dosages were less developed, but still notably better than controls. Histologic sections post 5-HT treatment revealed gonadal acini of the estradiol treated animals contained significant numbers of free oocytes and correlated with the animals that showed the greatest numbers of spawned oocytes. Germinal vesicles with distinct nucleol were present in all oocytes.

TABLE 2.

Estradiol treatment	Prominent genital canals # (%)	No genital canals # (%)	Total animals
controls (0 ng/g)	3 (6%)	48 (94%)	51
group 1 (37.5 ng/g)	11 (22%)	38 (78%)	49
group 2 (75 ng/g)	18 (34%)	35 (66%)	53

Control animals contained acini with necrotic oocytes even in animals that responded to 5-HT. In other controls, the ovarian mass was clearly degenerating, had few oocytes, and most of the germinal vesicles lacked a nucleolus and were vesiculated.

A series of oysters were treated with E_{17} , held for 14 days during the peak spawning period (May 2002), and examined for the presence of prominent genital canals (PGC). Treated animals showed significantly ($P < 0.001$) more individuals with prominent genital canals than control animals held under the same conditions and responded in a dose-response relation. In addition, of 265 triploid animals injected with E_{17} , 13 confirmed 3N females had developing oocytes compared to 0 of 160 untreated cohorts examined 1 year later. The overall response suggests that expansion of the methodology to determine better dose response curves, dose frequency, and response of animals will provide techniques that

are directly applicable to and useable by oyster hatchery industries for manipulating diploid and triploid broodstocks.

DISCOVERY OF GENE MARKERS THAT CAN BE USED TO RAISE THE PROFITABILITY OF ABALONE AQUACULTURE IN AUSTRALIA. Nick Robinson, Matt Baranski, Meaghan Rourke, and Ben Hayes.

Aquaculture is rapidly developing as a source of abalone for export in Australia. The aim of this study is to discover markers for genes of economic importance to the abalone industry in Australia. The most important traits to abalone farmers are rate of growth to market size, meat to shell ratio, and uniform size. Other traits of importance include flesh color, tiger patterning, texture, live product, shell shape, and frill dimensions. One hundred and fifty new microsatellite tests have been developed as part of this project. In order to maximize the power of this project to find markers affecting profitability, DNA from six full-sibling groups will be selectively pooled based on a "profit index" in which traits are weighted according to their $\$$ impact. Because growth rate will be a major influence in the index, and because the experimental animals have not yet grown to market size, pools of tentacle DNA from the fastest and slowest growing animals as at March 2003 were created and used to begin the experiment. Here we report on the sensitivity of the selective DNA pooling technique and on the differences that were detected between the pooled genotype profiles for fast and slow growing abalone.

TRENDS IN PINTO ABALONE *HALIOTIS KAMTSCHATKANA* ABUNDANCE AT TEN SITES IN THE SAN JUAN ISLANDS AND MANAGEMENT OF THE SPECIES IN WASHINGTON STATE. Don P. Rothaus, Robert E. Sizemore, Tina Rohela, Michael J. Ulrich, and Carolyn S. Friedman. School of Aquatic and Fishery Sciences, University of Washington, 1122 NE Boat Street, Seattle, WA 98195, USA. E-mail: carolynf@u.washington.edu

As a result of concerns regarding the stability of pinto abalone (*Haliotis kamtschatkana*) populations in Washington and the closure of the abalone fishery in neighboring British Columbia, Canada, the Washington Department of Fish and Wildlife (WDFW) established index stations at 10 sites in the San Juan Islands. These stations varied in size from 50 m² to 380 m², averaging about 220 m². WDFW divers systematically surveyed each of these stations in 1992, 1994, and 1996.

A decrease in total abalone abundance at these 10 index stations from 1992 to 1994 ($n = 351$ to $n = 288$), along with anecdotal information of population decline by University of Washington (UW) researchers and WDFW Enforcement personnel, resulted in the closure of the Washington pinto abalone fishery in 1994. Following the closure, a 2003 survey documented a decline from 351 in 1992 to 137 in 2003 and densities below or near

0.1/m². Research in other regions indicate that sedentary invertebrates, such as abalone, must be within 1.0–2.0 m of one another ($d \geq 0.33\text{--}0.15$ abalone/m²) for successful fertilization. However, given the gregarious nature of abalone, we examined the proximity of individuals to one another and observed that most animals were actually within 1–2 m of one another. At one site, of the 18 abalone observed and an average density of 0.1 per m², when the proximity of individuals to one another was measured, 44% were within 0.3 m of another abalone, 72% were within 1 m, 83% were within 2 m, 94% were within 3 m, and 100% were within 4 m of another individual within the index station. Based on survey data, and information from abalone fisheries around the world, it is clear that additional stock assessments are needed to analyze population trends and abalone behavior in Washington abalone stocks to best manage this species. Additional index sites, early juvenile life history, population genetics, and the potential for enhancement are also being examined in this study.

SUMMER MORTALITY IN THE PACIFIC OYSTER *CRASSOSTREA GIGAS*, OVERVIEW OF 3-YEAR RESULTS OF THE COOPERATIVE "MOREST" PROJECT. J. F. Samain, P. Boudry, L. Degremont, P. Soletchnik, M. Ropert, E. Bedier, J. L. Martin, J. Moal, M. Mathieu, S. Pouvreau, C. Lambert, J. M. Escoubas, J. L. Nicolas, F. Le Roux, T. Renault, T. Burgeot, and C. Bacher, Laboratoire IFREMER de Physiologie des Invertébrés, Centre de Brest. BP 70, 29280 Plouzané, France. E-mail: jfsamain@ifremer.fr

Summer mortality of *C. gigas* oyster is not yet clearly understood in literature. Complex interactions are suggested between environment, oysters, and pathogens. Such multifactorial event led us to organize a research network (including genetics, physiology, immunology, pathology, ecotoxicology, and environment) collaborating on the same natural or hatchery biological material. This strategy allowed to progressively classify importance of the different factors involved in the phenomena by coupling field and experimental studies.

A temperature over 19 °C is the first condition in France. This temperature is associated to *C. gigas* reproductive period. Defense responses are lowered during this reproductive stage contrary to sterile triploids that are mainly resistant, corroborating that reproduction is also a risky biological stage. A genetic component evidenced by divergent selection in two generations was confirmed the third year (Boudry et al. this meeting). Sensitive (S) and resistant (R) oysters in the same area or in controlled experimental conditions showed a difference in reproductive strategy faced to similar food conditions (Fig. 1).

High trophic conditions increased the oyster reproductive effort and so the risky phase as shown by a negative scope for growth and a higher sensitivity to bacterial challenges. However, some stresses were necessary to induce mortality when temperature and reproduction were in the risky window. A simple transfer of oyster

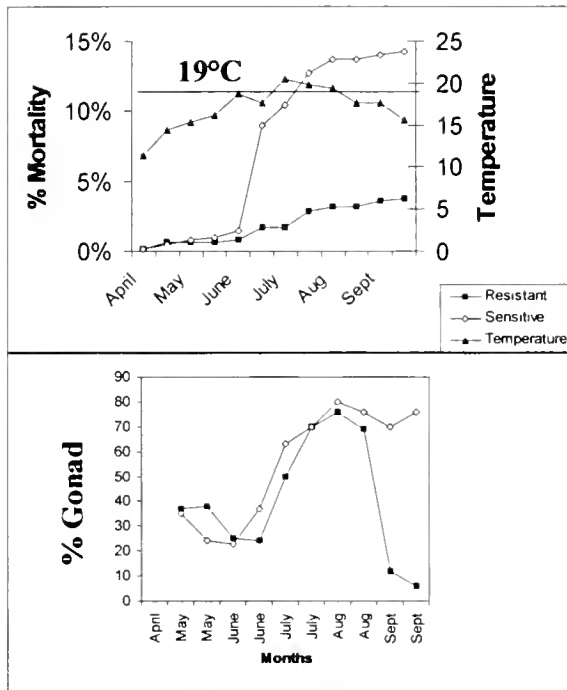

Figure 1. Up: cumulative mortality (%) of R and S oysters in the field (South Brittany) and water temperature (°C). Down: corresponding % gonad in the flesh (down).

induced mortality in these conditions. Sediment proximity appeared also as a detrimental factor, because oysters at 10 cm from sediment died contrary to oysters at 70 cm.

Different strains and species of vibrios were isolated from moribund oysters and determined by molecular techniques. Their virulence tested by injection in the muscle appeared variable according to strains and species. Effect of environmental factors on their virulence expression is also one among the key points under study.

USING PEARL OYSTERS AS HEAVY METAL MONITORS IN TROPICAL WATERS. Dale J. Sarver, Aaron Ellis, Neil Anthony Sims, and David Wise, Black Pearls, Inc., P.O. Box 525, Holualoa, HI 96725. E-mail: www.blackpearlsinc.com

Accurate and cost-effective methods are needed for monitoring heavy metal pollution levels in tropical oceans. Direct measurement of metals in seawater is inappropriate for most tropical ocean areas, as it requires regular sampling programs, expensive equipment, and sophisticated analytical expertise. Further, metal pollutants are usually sequestered in sediments, and water samples often miss the major peaks of exposure when sediments are resuspended during storms or other events. Because of these inadequacies, marine filter-feeding bivalves, such as mussels (*Mytilus edulis*), are widely used as bioaccumulators for marine pollution monitoring. The "Mussel Watch" system has proven very successful, and con-

tinues to be the most comprehensive measure of coastal marine metal pollution in the United States. However, these mussel and oyster species are limited to temperate water regions of the globe, and there are no comparable subjects for monitoring of oligotrophic tropical waters.

Our research results demonstrate that pearl oysters are the ideal warm-water complement to the "Mussel Watch" work. *Pinctada* spp are cosmopolitan in distribution, sessile, and long-lived. Initial trials have confirmed a phenomenal propensity to accumulate heavy metals in the Hawaiian pearl oyster (*P. margaritifera gaultsoffi*). In controlled tank trials, copper, cadmium, and zinc showed constant rates of bioaccumulation in pearl oyster tissues, directly proportional to the metals' concentration in the tank water, and the duration of exposure. These trials also established standards for field monitoring, with demonstration trials providing preliminary data from around the Hawaiian Islands. A second series of field trials underscored the significant temporal variability that typifies heavy metal monitoring.

Ongoing research is now expanding the range of metals to include strontium, cobalt, and lead. Monitoring levels of radioactive strontium and cobalt could be an invaluable tool in remediation and repopulation of atolls in the South Pacific (such as Bikini and Enewetak Atolls, in the Marshall Islands, Christmas Island, in Kiribati, or Muroroa, in French Polynesia), which were sites of earlier atmospheric and underground nuclear bomb tests by the United States, Britain, and France.

USING OYSTER REEF COMMUNITIES IN THE DESIGN OF ESTUARINE RESTORATION PROJECTS IN SOUTH FLORIDA. Michael Savarese, S. Gregory Tolley, and Aswani K. Volety, Florida Gulf Coast University, 10501 FGCU Blvd., Fort Myers, FL 33965, USA. E-mail: Msavares@fgcu.edu

Greater Everglades restoration in South Florida is the largest public works project in US history. Although most associate the Everglades with freshwater wetlands, restoration projects concern both terrestrial and estuarine habitats and focus on entire watersheds. The ultimate goal of Everglades restoration is to "get the water right"—to re-establish the pre-alteration quantity, quality, timing, and distribution of freshwater. The process is governed by a federally legislated partnership between the United States Army Corps of Engineers and the South Florida Water Management District and operates through consensus among numerous governmental agencies, NGOs, and university professionals. Restoration planning follows a strict protocol that includes both scientifically and managerially sound practices. As the downstream recipient of freshwater, estuaries have much to gain from watershed restoration. The American oyster, *Crassostrea virginica*, is being used as a bioindicator of estuarine health, as a tool for establishing restoration targets, and as a measure of restoration effectiveness. The purpose of our presentation is three-fold. First, the restoration protocol used in the Greater Everglades is reviewed. Second, the

usefulness of oyster reef biology and ecology to this process is demonstrated. Lastly, we illustrate this application with an example from an estuarine restoration project that is designed and awaiting authorization.

The protocol adopted for Everglades restoration consists of 9 steps: (1) defining restoration goals; (2) characterizing the current conditions; (3) establishing the pre-alteration state; (4) designing alternative restoration scenarios; (5) establishing performance measures and targets; (6) modeling to evaluate each scenario; (7) designing a restoration effectiveness monitoring plan; (8) implementing a restoration scenario; and (9) initiating adaptive management. Oysters and their reef communities are being used in steps 2, 3, 5, and 7. Various aspects of oyster physiology and ecology, including growth, standing stock, recruitment, susceptibility to disease, living density, the distribution and aerial extent of reefs, and the diversity and richness of the reef community, serve as bioindicators of estuarine health (step 2). These aspects are compared using a spatial homologue approach, whereby geomorphologically similar positions along the estuarine axis are compared among altered and pristine estuaries. Step 3 is achieved by comparing the present distribution of oyster reefs with pre-alteration, historical surveys. In the absence of such documents, the stable isotope and trace metal geochemistry of subfossil oyster shells can be used to infer paleosalinity. The same aspects of physiology and ecology are used to define targets and performance measures of the restoration project (step 5). Finally the restoration project's success can be gauged (step 7) by how close the system approaches a given target.

FIRST HARVEST OF BLACK PEARLS FROM THE IMPERILED NATIVE HAWAIIAN PEARL OYSTER *PINCTADA MARGARITIFERA GALTISOFFI*. Neil Anthony Sims and Dale J. Sarver, Black Pearls, Inc., P.O. Box 525, Holualoa, HI 96725, USA. E-mail: www.blackpearlsinc.com

The native Hawaiian black-lip pearl oyster, *Pinctada margaritifera galtsoffi*, is a distinct, endemic subspecies of the fabled Tahitian pearl oyster, *P. margaritifera*. The Hawaiian pearl oyster was once common, and was traditionally used by Hawaiians in making fishing hooks and lures, other tools, and ornaments. The oyster has become increasingly rare since Western contact, due primarily to commercial fishing. The last significant stocks of *P. margaritifera galtsoffi* were fished out at Pearl and Hermes Reef in the 1920s, when over 100 tons of pearl shell were taken from this shallow, open lagoon. Recent surveys by NMFS divers found only 30 adult shells in over 18 diver-hours. All of these oysters were above 20 cm shell diameter, suggesting that recruitment is negligible. Stocks remain uncommon around the main Hawaiian islands, despite legal protection. Relict stocks in a few areas, such as Kaneohe Bay, still show decline.

Although hatchery techniques are now well-established for this species, stock recovery in Hawaii is limited by heavy predation on

the reef, pilfering by divers, pollution in protected reef and lagoon areas, and low water-residence time for larvae in open reef systems. Predation by fish and octopi is very heavy. Grow-out trials in protective cages left oysters vulnerable to *Cyathium* and other predatory snails settling out of the plankton. The most effective stock re-establishment plan would therefore be to set up reproductive reserves of large, densely-aggregated, older adult oysters. A "reproductive node" of closely-packed, highly fecund animals would be able to synchronize spawning and achieve high fertilization rates, resulting in large numbers of larvae. These larvae would then be dispersed by currents, eventually settling out naturally onto the reefs and lagoons throughout the group. Serendipitously (or otherwise), such a "reproductive node" can be provided almost precisely by a commercial pearl farm operation.

Black Pearls, Inc. (BPI) has therefore been developing the concept of Hawaii's first pearl farm as both a commercial business and a conservation tool. In essence, the pearl farm becomes a financially-self-sustaining (or profitable) means for resource enhancement. BPI assisted in the rewriting of Hawaii's ocean leasing legislation, and has since completed the lease application process for a 75-acre area next to Honolulu's International Airport. In 2003, BPI harvested the first genuine "Hawaiian pearls" from this site. This now provides a distinctive line of local pearls and pearl shell jewelry, an opportunity for Native Hawaiian artisans to once again work with their local material, and an added romantic allure to the islands.

MANAGING *PERKINSUS MARINUS* IN THE GULF OF MEXICO: THE DERMOWATCH PROGRAM. Thomas M. Soniat, Mason Foret, Department of Biology, Nicholls State University, Thibodaux, LA 70310; Sammy M. Ray, Department of Marine Biology, Texas A&M University at Galveston, Galveston, TX 77553; Enrique V. Kortright, Kortright Corporation, 102 Allendale Dr., Thibodaux, LA 70301; Lance Robinson, Texas Parks & Wildlife Department, 1018 Todville Rd., Seabrook, TX 77586, USA.

Throughout its range from Mexico to Maine, *Perkinsus marinus* is a major cause of mortality in eastern oysters, *Crassostrea virginica*. The parasite was first described from Louisiana oysters as *Dermocystidium marinum*, from which its common name "Dermo" is derived. Because there is no economical or feasible treatment of infected oysters, the only effective approach to control Dermo is proper management. The parasite is more prevalent at high water temperature (T) and high salinity (S) and is thus most problematic during late summer and on the seaward side of estuaries. Possible management techniques include maintaining freshwater inflows, diverting fresh water into high-salinity estuaries, early harvest of infected oysters, and moving infected oysters to low salinity waters. (The movement of infected oysters to low salinity environments is not recommended in estuaries lacking

frequent freshets, because this practice may lead to the long-term establishment of the parasite in the upper estuary).

The DermoWatch Program was established to more effectively manage Dermo in the Gulf of Mexico. DermoWatch is a web site (www.blueblee.com/dermo), a monitoring program, and an online community for the management of *P. marinus*. The web site contains an embedded model that calculates a time to critical level (t-crit) of disease from an initial level of disease and water T and S. Thus, samples of oysters are collected and water T and S are measured. An initial weighted incidence (i-WI) of parasitism is determined using Ray's fluid thioglycollate method. A critical WI (c-WI) is set at 1.5. Water T, S, i-WI are inputs to the model and by simulation a t-crit is determined as the number of days to reach c-WI, assuming no change in T or S.

Six public reefs and three private leases in Galveston Bay have been sampled monthly since December 1998. New Texas sites and Louisiana sites are being added. The web site displays the most recent data from each site on the home page and archives all data, such that an historical record is maintained. A web-accessible "Dermo Calculator" provides anyone with data on T, S, and i-WI the opportunity to calculate a t-crit and explore the dynamics of disease progression.

An obvious limitation of the approach is that single values of T and S, taken at the time the oysters are sampled, are used to represent environmental conditions for the entire month. We are testing the utility of a continuous monitoring station to better predict disease progression (<http://weather.lumcon.edu/stationdata.asp?stationid=105>). Studies are also being conducted on the relationship of levels of disease (WI) to oyster mortality. A clearer understanding of the relationship between WI and mortality will help us to more precisely establish a c-WI.

NUCLEUS QUALITY AND SUBSTITUTE OF ROUTINE SHELL. Ajai K. Sonkar, Pearl Aquaculture Research Foundation, 557/470, Old Katra Allahabad 211 002, India.

A study was undertaken to answer several questions for the particularity of the shell for the nuclei of pearls such as properties of a suitable nucleus, what makes nucleus perfect for seeding in an oyster...its hardness? Its density? Its surface smoothness? Its color? Or its brightness?

Why is freshwater shell only suitable for nuclei, does it affect the pearl quality? Or is it suitable because it is easy to drill? Does shell of the nuclei decide the quality of pearl or acceptability by the recipient oyster? With a nucleus cut from saline water shell can equal ability to be drilled and perfect surface smoothness and similar in all above factors produce a similar quality of pearl?

The author tested several shells from both saline and freshwater to find a substitute for the routinely used freshwater shell and received interesting results. All above aspects of the nucleus and the results of the experiments/comparison tests are discussed in the paper.

Figure 1. Nuclei cut from other than routine shells.

A COMPARISON OF RECRUITMENT ON MID-WATER OYSTER SPAT COLLECTORS AND SUBSEQUENT BOTTOM RECRUITMENT IN THREE SUB ESTUARIES OF THE CHESAPEAKE BAY, VIRGINIA. M. Southworth and R. Mann, School of Marine Science, Virginia Institute of Marine Science, College of William and Mary, Gloucester Point, VA 23062, USA.

Shellstrings have been used as oyster spat collectors for over 40 years to estimate potential bottom recruitment of oysters in many of Virginia's sub estuaries. Until recently quantitative estimators of subsequent bottom recruitment have been lacking. We offer a comparison of estimates of cumulative spat recruitment obtained from shellstrings throughout the settlement period (recorded on a weekly basis as the number of spat per shell and then totaled over the course of the settlement period) and quantitative estimates of spat settlement obtained from patent tong sampling in the subsequent fall. Comparisons include co-located stations collected over a 5-year period in the James River (8 stations), Piankatank River (7 stations), and the Great Wicomico River (6 stations) from 1998 to 2002. We examine the following aspects of the spat collector to benthic recruitment relationship: all data irrespective of source and year, location specific relationships (within and between rivers), the temporal effects of settlement on subsequent recruitment, and absolute levels of settlement on subsequent recruitment.

RECOMMENDATIONS FOR CULTURING JUVENILE QUEEN CONCH *STROMBUS GIGAS* FOR RESTOCKING AND COMMERCIAL PURPOSES. Ashley Spring and Megan Davis, Florida Institute of Technology, Biology Department, 150 West University Blvd., Melbourne, FL 32901, USA. E-mail: aspring@hboi.edu

Queen conch, *Strombus gigas*, are overfished throughout Florida and the Caribbean. In an attempt to curtail the depleted wild stocks, queen conch aquaculture has developed through the last 40 years. Whether the goal is to culture queen conch for stock enhancement, the seafood market, or the aquarium trade, there remain a number of fundamental aquaculture methods to improve

upon to enhance the quality of cultured conch and reduce costs. This study aims to improve survival, growth, shell strength, and culture costs of juvenile queen conch by manipulating stocking density and tank substrate. Three experiments were designed to test the effects of five stocking densities (20, 50, 75, 200, and 400 conch/m²) and three tank substrates (crushed coral aragonite, plastic liner, and aragonite chips) in recirculating water systems over 16 months.

Conch grown at low densities grew significantly faster (0.11–0.13 mm/day) than conch grown at high densities (0.06–0.08 mm/day). On the other hand, conch grown at high densities possessed significantly stronger shells. High mortalities occurred in conch grown on plastic liner (60%) versus aragonite chips (97%) and crushed coral aragonite (91%). There were no differences in growth between conch grown on the two sand substrates. Crushed coral aragonite costs one-third of the price of aragonite chips and is therefore suggested as a less expensive substrate option.

To culture juvenile queen conch for stock enhancement purposes, it is recommended that conch are grown at a stocking density of 200–400 conch/m² to provide the animals with the strongest shell strengths and on aragonite chips, which may increase burial rates. Commercial markets are not concerned with shell morphology; therefore, the fastest and least expensive culture conditions are recommended. Conch grown for the seafood market and the aquarium trade will grow the fastest at stocking densities of 20–50 conch/m² and can be grown inexpensively on crushed coral aragonite. The recommended culture conditions may benefit aquaculture facilities, fishery managers, and commercial industries with higher quality stocks at lower costs.

INDUCED TRIPLOIDY IN THE BAY SCALLOP *ARGOPECTEN IRRADIANS* AND EARLY FIELD CULTURE PERFORMANCE. Amandine S. Surier* and Richard C. Karney, Martha's Vineyard Shellfish Group, PO Box 1552, Oak Bluffs, MA 02557, USA. E-mail: mvsg@capecod.net

Triploidy is the condition of possessing three times the haploid number of chromosomes in the cell nucleus. This condition can be induced by cell treatment, in the early stages of development. Not to be confused with controversial, transgenic genetically-modified organisms (GMO's), polyploidy is simply an increase in the number of a single organism's chromosomes, with no introduction of foreign genetic material. Triploid animals and plants are usually sterile because of the inability of homologous chromosomes to synapse in meiosis. As a result of their sterility, they tend to divert the energy usually used for reproduction towards somatic growth. Because of this unique quality, triploid bivalve production has attracted worldwide attention since the early 1980's. At present triploidy has been successfully applied to the economic benefit of the Pacific oyster industry on the west coast of the US and also in France.

Triploidy in scallops has been investigated in several species over the past 20 years. Overall, research suggests that the development of a triploid bay scallop will result in an increased growth rate, a larger adductor muscle mass and an increased hardness with regard to stressful environmental conditions.

To test this hypothesis, triploidy was induced in the bay scallop *Argopecten irradians* under funding from the Northeastern Regional Aquaculture Center. The newly fertilized eggs were treated with a low risk chemical, 6-DMAP, that has been shown to be slightly less efficient than Cytochalasin B but much safer to handle as well as being water soluble. The success of induction was measured by flow cytometry at the Virginia Institute of Marine Science. Triploidy was induced on five occasions during the 2003 culture season. Each batch of eggs was treated 15 to 25 minutes post fertilization for approximately 11 minutes with a treatment concentration of 400 µM. The results ranged from 77% up to 100% triploidy in the first week of development. In late August, early September, juveniles from the last two spawns were deployed in growth trials in Katama Bay on Martha's Vineyard, MA, Buzzards Bay on Cape Cod, MA, in Point Judith Pond, RI, and in Cedar Beach on eastern Long Island, NY. Shell growth was measured every other week at each site until the end of the growing season. There was no significant difference in juvenile shell growth between triploids and diploids at any of the sites. The animals were overwintered in pearl nets. The survivors will be deployed in the spring for further growth monitoring, and adductor muscle weight and gonad development analyses.

REFOCUSING THE AMERICAN LOBSTER (*HOMARUS AMERICANUS*) STOCK ENHANCEMENT PROGRAM. M. Tlusty, New England Aquarium, Central Wharf, Boston MA 02110, USA. E-mail: mtlusty@neaq.org

The American lobster (*Homarus americanus*) stock enhancement program is currently non-existent. Although stock managers have been able to culture this species in captivity for over a century, attempts to enhance wild stocks have largely failed. This is in direct opposition to the European lobster (*H. gammarus*), which can and is being successfully enhanced. The best example for this species is in Norway where 50% of the fishery landings are of animals that began life in a hatchery.

The respective success and failure of the European and American strategies was directly influenced by the respective management strategies. The strategy of the American lobster stock enhancement program was to rear a large number of fourth stage, early benthic juveniles. In contrast, European programs rear fewer animals but for a longer period. Animals are reared for up to a year, to the ninth or twelfth stage. The biologic basis for the success and failure of the respective programs will be discussed.

To refocus the American lobster stock-enhancement program, the management philosophy needs to be shifted to rear animals to later stages. Part of the reluctance in making this shift was the

Figure 1. The survivorship of juveniles (beginning with stage IV animals) fed one of four different diets. Diets are frozen *Artemia* (B), or the commercial *Artemia* replacement (CAR) diets Artemac (A), Economac (E), or Progression (P).

higher cost of the longer hatchery phase. Thus, refocusing will entail creating a cost effective rearing environment, which needs to be demonstrated. At the New England Aquarium, research is being conducted on creating a cost effective rearing environment. A rearing method was developed that can grow lobsters individually to ninth stage at a density of 400/m², compared to approximately 150/m² for European lobsters in communal culture, and 10/m² in the wild. In addition, the use of commercial *Artemia* replacement diets is being investigated for their role in decreasing the cost of producing older animals (Fig. 1). Demonstrating the ease of individual rearing, the availability of commercially available formulated feeds, and a decreased cost of production are the first steps necessary in refocusing the American lobster stock enhancement program.

These are the first steps necessary in refocusing the American lobster stock enhancement program. Future efforts will include examining the performance of hatchery animals reared on commercial *Artemia* replacement diets when released into the wild, and determine full-scale economic production scenarios. Based on the recent advanced in decreasing the cost of producing later staged juveniles, the future for American lobster stock enhancement is very promising.

ASSESSING ENVIRONMENTAL IMPACTS OF AMERICAN LOBSTERS IMPOUNDMENTS IN COASTAL MAINE, USA. Michael Tlusty, New England Aquarium, Central Wharf Boston, MA 02110, USA. E-mail: mtlusty@neaq.org

In the American lobster fishery, animals caught in the fall are held live in dammed tidal areas known as impoundments. They are a critical part of the fishery, as they prevent a market glut in the fall, enabling constant supplies of animals through the winter. In the United States, Maine has 65 impoundments, with a combined capacity of 2,600 metric tons. While impounded, lobsters are fed leading to a substantial input of organic matter. As with other aquaculture operations, this can potentially impact the environment through increased sedimentation rates, and the creation of anoxic sediments. Although these impoundments have been operating for more than a century, there are no requirements for envi-

ronmental monitoring, and have been no studies of the impacts of these areas.

In 1999 and 2000, nine lobster pounds and reference areas were monitored in southern Maine to determine the flow of organic matter through these areas. Macrofauna and microfauna were also monitored to assess subsequent environmental effects. Impoundments had little to no measurable impact on the accumulation of organic matter. Lobster feed was nearly 90% organic matter (loss on ignition at 500 °C), whereas feces ranged from 20%–40% depending on feeding frequency and temperature. Benthic organic matter ranged from 1.5%–7%. There was no discernable trend if values were greater inside compared to outside the pound. Overall, the holding of American lobsters at high densities in impoundments is not resulting in a large amount of organic matter being deposited to the benthos. Possible reasons for this include rapid water recycling, frequent exposure to air, and long fallow periods every year.

MANAGING OYSTER REEFS FOR ECOLOGICAL FUNCTION: FACTORS INFLUENCING HABITAT QUALITY FOR REEF-RESIDENT COMMUNITIES. S. Gregory Tolley, Aswani K. Volety, and Mike Savarese, Florida Gulf Coast University, College of Arts and Sciences, 10501 FGCU Blvd South, Fort Myers, FL 33965, USA. E-mail: gtolley@fgcu.edu

To gauge the influence of freshwater inflow on the habitat value of oyster reefs, spatial and seasonal patterns of the presence of reef-resident fishes and decapods were assessed in the Caloosahatchee, Estero, and Faka-Union estuaries of Southwest Florida. Lift nets (1 m² containing 5 L of oyster clusters) were deployed on intertidal reefs at three sites along the salinity gradient of each estuary. Nets were deployed during three seasonally dry and three seasonally wet months for a period of 30 d. Oyster densities were estimated at each site and a number of community metrics were calculated as a measure of habitat value (eg, abundance, biomass, presence of oyster-dependent organisms, diversity, dominance, and richness).

Several metrics trended downstream in one or more systems (eg, abundance and biomass increased downstream in all three systems, and measures of biodiversity were higher downstream in

the Caloosahatchee) and seemed to be unrelated to the density of living oysters present. Although abundance was higher during the wet season for all three systems, biomass was lower during this season in the Caloosahatchee. In the Caloosahatchee and the Estero, measures of biodiversity were higher during the dry season. A number of metrics were positively correlated with salinity in one or more systems: biomass, biodiversity (Fig. 1), and the presence of oyster dependent species. Additional data collected in the Caloosahatchee demonstrated that some metrics were also related to freshwater inflow; for example, biomass and biodiversity varied inversely with inflow recorded during the sampling period as well as with inflow recorded at time lags of up to 3 to 4 months.

Figure 1. Relationship between diversity of reef residents and salinity of capture in the Caloosahatchee estuary.

These results suggest that regulated freshwater releases can be a useful tool for managing Southwest Florida oyster reefs, but that resource managers should consider the habitat requirements of oyster-reef organisms in addition to those of the oysters themselves when establishing release guidelines.

ROLE OF ANTHROPOGENIC AND ENVIRONMENTAL VARIABILITY ON THE PHYSIOLOGICAL AND ECOLOGICAL RESPONSES OF OYSTERS IN SOUTHWEST FLORIDA ESTUARIES. K. Aswani, S. Volety, Gregory Tolley, Michael Savarese, and James T. Winstead, Florida Gulf Coast University, 10501 FGCU Blvd., Fort Myers, FL 33965, USA. E-mail: avolety@fgcu.edu

The role of freshwater alterations and seasonal changes on the ecological and physiological responses of oysters were investigated in the Caloosahatchee River, Estero Bay and Faka-Union

estuaries in SW Florida. Condition index, oyster density, and disease incidence of *Perkinsus marinus* were measured through monthly sampling at three comparable sites located along the main salinity gradient in Estero Bay and Faka-Union estuary, while spat recruitment, juvenile growth, and gonadal index of oysters were also measured monthly at five locations along the salinity gradient from the Caloosahatchee River.

Sharp declines in temperatures and salinities resulted in decreased *P. marinus* infections in oysters from all locations. Antagonistic effects of temperature and salinity on *P. marinus* infections make trends difficult to discern. Oysters from Faka-Union, an estuary that receives excessive freshwater, have a significantly lower condition index compared to a more natural estuary, Estero Bay (Fig. 1).

Figure 1. Condition index of oysters from the Faka-Union (FU) and Estero Bay (EB) estuaries. Stations 1, 2, and 3 are from upstream to downstream.

Condition index in oysters from all three estuaries was influenced by the reproductive activity. Oyster density was higher in the upper-mid estuary and decreased with increasing distance offshore in the Estero Bay and the Caloosahatchee River, whereas none to few oysters are present at the upstream locations in the Faka-Union estuary. Only the downstream-most site showed appreciable living densities, a pattern consistent with predicted effects of watershed alteration and freshwater inundation. Oysters in SW Florida estuaries seem to continuously spawn between March/April to October, with upstream oysters spawning earlier than the downstream oysters. Freshwater releases from Lake Okeechobee into the Caloosahatchee River in spring/summer months resulted in >95% mortality of juvenile oysters and pushed the loci of spat recruitment to more downstream locations.

We are communicating the results of our study with resource managers who are utilizing them to adjust the quantity and timing of freshwater releases into the estuaries. The use of adaptive man-

agement approaches involving freshwater releases to sustain and enhance oyster populations is valuable to the ecology of SW Florida estuaries.

LOCALIZATION OF TAACC REPEATS TO TELOMERES OF *PENAEUS VANNAMEI* CHROMOSOMES BY FISH.

Yongping Wang, Ximing Guo, Haskin Shellfish Research Laboratory, Institute of Marine and Coastal Sciences, Rutgers University, 6959 Miller Avenue, Port Morris, NJ 08349 USA; **Acacia Aleivar-Warren**, Environmental and Comparative Genomics Section, Department of Environmental and Population Health, Tufts University School of Veterinary Medicine, 200 Westboro Road, North Grafton, MA 01536, USA; and **Linghua Zhou, Jianhai Xiang, and Yongping Wang**, Institute of Oceanology, Experimental Marine Biology Laboratory, Chinese Academy of Sciences, 7 Nanhai Road, Qingdao 266071, China.

Telomeres are the protein-DNA structures at ends of linear chromosomes. They protect chromosomes from degradation and end-to-end fusion, rearrangement and chromosome loss. Telomeres may play an important role in aging and oncogenesis. Telomeric DNA usually consists of tandem repeats of a very simple sequence about 5–10 bp in length, which are often highly conserved across taxa. All vertebrates studied so far, as well as some other organisms such as protozoa *Trypanosoma* and several slime molds and fungi, share the same telomere sequence (TTAGGG)_n. Telomere sequences in marine invertebrates are not extensively studied. Two groups of ciliates, *Tetrahymena* and *Oxytricha*, have different telomeric sequences of (TTGGGG)_n and (TTTTGGGG)_n respectively. In mollusks, 10 bivalves studied so far contain the vertebrate sequence, (TTAGGG)_n.

In this study, TAACC repeats were localized to telomeres of *Penaens vannamei* chromosomes by fluorescence *in situ* hybridization (FISH). Clones containing TAACC repeats were identified by sequencing, and primers were designed to amplify DNA fragments containing TAACC repeats. Four FISH probes, P1-P4, containing different numbers of TAACC repeats were produced by PCR amplification and labeled by incorporation of digoxigenin-11-dUTP during PCR. Metaphase material was prepared from testis. The chromosome number of *P. vannamei* was confirmed as $N = 44$. All four probes produced positive FISH signals on telomeres of *P. vannamei* chromosomes. A few chromosomes had positive signals interstitially. The four probes differed considerably in signal strength and chromosome coverage. Despite some variation, signal strength and chromosome coverage of the four probes were in the general order of $P1 > P2 > P3 > P4$, which correlated nicely with the length of TAACC repeats within the four probes: 83, 66, 35, and 30 bp, respectively. The correlation between signal strength/chromosomal coverage and the length of TAACC repeats suggests that TAACC repeats, rather than flanking sequences, produced the FISH signals at chromosome ends, and TAACC is likely the telomere sequences for *P. vannamei*.

PRODUCTION AND EVALUATION OF ALL-TRIPLOID AND DISEASE-RESISTANT EASTERN OYSTERS FOR AQUACULTURE. **Yongping Wang, Ximing Guo, Gregory DeBrosse, and Susan Ford**, Haskin Shellfish Research Laboratory, Institute of Marine and Coastal Sciences, Rutgers University, 6959 Miller Avenue, Port Norris, NJ 08349, USA. E-mail: wang@hsrl.rutgers.edu

The eastern oyster (*Crassostrea virginica*) faces two major diseases: MSX (caused by the parasite *Haplosporidium nelsoni*) and Dermo (caused by the parasite *Perkinsus marinus*). Rutgers University has been breeding oysters for disease-resistance since the early 1960s. Strains resulting from the Rutgers breeding program have shown strong resistance to MSX and recently some resistance to Dermo. Because the Rutgers strains are superior in disease-resistance, they do not grow as fast as some of the commercial strains, such as the Flower's Oyster Company's strain (which shows little resistance to MSX and Dermo). Growth improvement of the Rutgers disease-resistant strains is needed to maximize return for oyster farmers. Fast growth means reduced culture duration/cost, and exposure to diseases. We recently developed tetraploid oysters from the Rutgers disease-resistant strains. The goal of this study is to produce natural triploids from the disease-resistant tetraploid stocks and compare their growth and survival to that of normal diploids and chemically induced triploids. Triploids grow significantly faster than diploids in most mollusks studied so far.

Three replicates of 3 groups were produced from Rutgers disease-resistant stocks: (1) diploid control (2N); (2) triploids induced by blocking polar body II with cytochalasin B (3nCB); and (3) natural triploids produced by diploid female x tetraploid male crosses (3nDT). The 3nCB groups produced 72% triploids on average, and the 3nDT groups produced 98% triploids. Oysters from 3nCB and 3nDT groups were combined with diploid controls so that the combined groups contained approximately 50% diploids and 50% triploids from either 3nCB or 3nDT groups. The diploids served as internal controls, and growth comparison was made only after ploidy determination for each individual. No significant difference in growth and survival was detected between diploids and 3nCB or 3nDT triploids at 1 year of age. Another sampling is scheduled at 18 months, and data will be presented.

CONSERVATION AND LIFE HISTORY STRATEGIES OF ENDANGERED AND AT RISK SPECIES OF ALASMIDONTA (BIVALVIA, UNIONIDAE). **Barry J. Wicklow**, Department of Biology, Saint Anselm College, Manchester, New Hampshire 03102, USA. E-mail: bwicklow@anselm.edu

Freshwater mussels suffered astonishing declines in diversity, abundance, and distribution within the last 200 years. In the genus *Alasmidonta*, 9 of 13 species are threatened, endangered or extinct. Here I compare the complex life histories of the dwarf wedgemussel, *A. heterodon* (federally endangered), the brook floater, *A. varicosa* (state endangered throughout most of its range), and the

triangle floater, *A. undulata* (stable or special concern in the NE, threatened or endangered in the SE). New Hampshire glochidial release periods are from early March to June for *A. heterodon*, mid-April to May for *A. varicosa*, late April to June for *A. undulata*. The only *Alasmidonta* species using a behavioral display to attract host fishes is *A. heterodon* which utilizes as host species the tessellated darter, *Etheostoma olmstedii*, the slimy sculpin, *Cottus cognatus*, and the Atlantic salmon, *Salmo salar* in the NE. *A. varicosa* and *A. undulata* use a wider range of host fish species. Long-term studies show human associated population density declines of *A. varicosa*. Human impacts, including stream fragmentation, disrupt life cycles, prevent host fish migration, block gene flow, and prohibit recolonization resulting in reduced recruitment rates, decreased population densities, and increased probability of local extinction.

DEVELOPMENT OF SECURE REARING SYSTEMS FOR DOMESTICATED BIVALVE BROODSTOCK. Gary H. Wikfors, James C. Widman, Barry C. Smith, David Veilleux, Joseph Choromanski, Shannon L. Meseck, Ronald Goldberg, and Sheila Stiles, NOAA Fisheries and Ecosystems, NEFSC, 212 Rogers Avenue, Milford, CT 06460, USA.

An intensive, land-based nursery culture system using recirculating water principles is being designed and tested for post-set bivalves. One additional potential application of such a system is to secure valuable genetic resources, such as domesticated broodstock. These genetic resources could be threatened by uncontrolled environmental events such as storms, disease outbreaks, harmful algal blooms, pollutant spills, etc. Accordingly, a rearing environment for highly specialized broodstock is needed that is more secure and dependable than nature provides.

A recirculating system for bivalves faces some of the same imperatives as finfish systems, (eg, the need to maintain chemical and biological water quality) however, some challenges are unique to bivalves. First, a nutritionally complete diet must be available continuously; second, biofilters and aeration need to be effective in maintaining chemical water quality without consuming the small feed particles used by bivalves; and third, respiratory and nutritional needs of the shellfish must be balanced such that food is not filtered wastefully to maintain respiration rates. Our land-based, recirculating seawater bivalve rearing system consists of: (1) a solar microalgal culture unit, (2) a shellfish-rearing unit with several different biofilter options, and (3) a seawater discharge treatment unit using seaweed to remove dissolved nutrients from the waste stream. Although the system design and operation have not yet been optimized, experiments have been conducted to test and parameterize automated monitoring and process control protocols

for the three component units. Findings—and remaining problems—identified in our research thus far will be summarized.

THE NORTHERN QUAHOG *MERCENARIA MERCENARIA* HAS SLOWER GROWTH AND POORER CONVERSION EFFICIENCY THAN OYSTERS OR SCALLOPS FED IDENTICAL DIETARY RATIONS AND REGIMES. Gary H. Wikfors, Jennifer H. Alix, Mark S. Dixon, and Barry C. Smith, NOAA, National Marine Fisheries Service, NEFSC, 212 Rogers Avenue, Milford, CT 06460, USA.

We have conducted feeding experiments with post-set eastern oysters, *Crassostrea virginica*, northern bay scallops, *Argopecten irradians irradians*, and northern quahogs, *Mercenaria mercenaria*, in which we varied quantity and distribution in time of a cultured microalgal feed (mix of two *Tetraselmis* strains) in a factorial grid. Computer-automated molluscan rearing chambers, discontinuously fed downwellers in which shellfish rest on a nylon mesh screen, were used to control feeding parameters. By measuring growth and system feed conversion efficiency (the percentage of microalgal biomass, provided that is incorporated into shellfish soft tissues), we sought feeding rations and regimes that would optimize either growth or conversion efficiency. With this information, feeding strategies based on economic considerations balancing microalgal costs and system-operation costs could be developed for intensive, land based nursery culture of these shellfish.

Results for oysters and scallops were consistent; growth was optimal at a 5% (of shellfish live weight in dry weight algae per day) ration, but conversion efficiency was optimal with a 2% ration, with best results always obtained on the most-frequent feeding regime of $\times 16$ per day. By contrast, quahog clams grew much more slowly on the same rations and regimes of the same microalgal diet, had lower conversion efficiencies, and showed no benefit of more-frequent feeding at rations that supported positive growth. A 10% ration produced the highest growth and conversion efficiencies, but this was the highest ration tested; therefore, the optimum may be higher. From this comparison of oysters, scallops, and clams subjected to identical experimental feeding conditions, we suggest several possible interpretations:

1. Clams require much more food than oysters or scallops
2. The quality of the *Tetraselmis* diet was poor for clams, compared to oysters and scallops
3. Little of the algae was consumed by the clams, because
4. Clam filtration rates are much lower than rates for the other shellfish, or
5. The rearing environment was not appropriate for clams

Support for all of these hypotheses can be found in previous studies. The overall conclusion is that quahogs appear to be poorly suited to intensive, land-based nursery production on the cultured algal diets that work well for oysters and scallops.

PELLETED DRY FEEDS FOR JUVENILE TROPICAL ROCK LOBSTER *PANULIRUS ORNATUS* THAT OUTPERFORM MUSSELS. Kevin C. Williams, David M. Smith, Margaret C. Barclay and Simon J. Irvin, CSIRO Marine Research, 233 Middle Street, Cleveland Queensland 4163, Australia. E-mail: Kevin.williams@csiro.au

On-growing of tropical rock lobster *Panulirus ornatus* from wild seed is a thriving aquaculture industry in SE Asia, notably Vietnam where current annual production is estimated at 2,000 t. Culture relies on feeding small crabs, paddy snail, oysters and fish bycatch. The dwindling supply of these feeds and the downstream impacts of their use are of increasing concern to aquaculturists and environmentalists alike. A cost-effective pelleted feed that enables lobsters to grow rapidly to marketable size is a high priority. Previous studies at this laboratory showed that juvenile *P. ornatus* readily ate dry feed pellets and that growth exhibited a clear dose dependent response to dietary protein content. However, even on the best performing laboratory-made feeds, lobsters grew only at 60% of the rate achieved in the wild. This sub-optimal growth was attributed to a rapid loss of the pelleted feed's attractiveness upon immersion in water. To understand why this attractiveness was lost so quickly, we quantified the nature of chemical loss from immersed feeds and correlated this to the lobster's preference for these feeds.

The leaching loss from thawed frozen green lip mussel *Perna canaliculus* (GM), pelleted feeds (PFs) containing homogenates of either GM, fresh prawn *Metapenaeus bennettiae*, bloodworm *Marphysa sanguinea*, or squid *Sepioteuthis spp* (each included at 50 g kg⁻¹ dry matter (DM)) and a commercial kuruma shrimp feed (KF) were examined after immersion in water for up to 7.5 h. DM loss from GM was 27% for 0–1 h and a further 7% over the next 6.5 h as compared to losses of 7%–10% in the first h and a further 3%–8% in the next 6.5 h for PFs and KF. For the 0–1 h period, loss of Kjeldahl N, trichloroacetic acid-soluble protein (TCA-P) and total free amino acids from GM was from 2.5 to 6-fold greater than from KF with losses from PFs being slightly less. These differences lessened with increased immersion time. PFs and GM were individually preference-tested ($n = 6$) against KF, either after the same pre-soaking period or when non-soaked. Lobsters' preference for PFs and KF was always less than for GM, irrespective of whether or not KF was soaked, and independent of immersion time. Regression analysis identified TCA-P, glycine and taurine as the principal components influencing the lobster's feeding preference.

These results suggested that using a peptide-rich ingredient such as krill hydrolysate might enhance the lobster's consumption of pelleted feeds. This was confirmed by using it at a constant 8% of formulation in two growth assays: an 8-week dietary protein requirement study (five increments and GM; $n = 4$) and a 12-week dietary astaxanthin requirement study (four increments, GM and blue mussel *Mytilus edulis* (BM); $n = 4$). In the first assay

with 1.9 g lobsters, those fed the highest protein feed (61%, DM) grew twice as fast as those fed GM (0.91 and 0.42 g/wk, respectively). In the second assay with 18 g lobsters, those fed the pelleted feeds grew faster than those fed either GM or BM (2.81–3.26, 2.54, and 1.74 g/wk, respectively).

PATTERNS OF REPRODUCTION AND SPAWNING BEHAVIOUR FOR SCALLOPS *PECTEN NOVAEZELANDIAE* IN NORTHEASTERN NEW ZEALAND. James R. Williams and Russell C. Babcock, Leigh Marine Laboratory, University of Auckland, PO Box 349, Warkworth, New Zealand.

Studies of reproduction in free-spawning marine invertebrates usually involve repeated destructive sampling from a population to measure changes in mean gonad condition. This sampling makes it virtually impossible to answer questions such as: Do entire populations spawn synchronously or sequentially in groups? Do individuals spawn repeatedly? Do gonads redevelop between spawnings? Answers to these questions are vital to enable us to accurately estimate total egg production, probability of fertilization, and the timing of spawning in relation to key environmental signals. In the scallop *Pecten novaezelandiae*, the developmental stage of the gonad can also be assessed without harming the animal, making sequential measurements within individuals possible.

In this study, reproduction in scallops was measured in four populations in the Hauraki Gulf, New Zealand from 2000 to 2003. A macroscopic gonad visual grade (VG) was developed and validated by regressing VG with quantitative histological data ($r^2 = 0.80–0.87$). Changes in VG, gonad mass, and histology were measured in scallops destructively sampled to describe variation within and among populations. In two of the populations, tagged scallops tethered to the seabed were also monitored and changes in VG were compared to data from destructive samples.

The *in situ* VG data revealed that scallops participated in multiple spawning events within a reproductive season. Spawning synchrony within a patch varied from 0%–75%. Partial spawnings were common, and gonads redeveloped between spawnings. This is the first study to describe the seasonal reproductive behavior of individuals from a non-colonial, free-spawning taxon. Spawning events were correlated with environmental variables to indicate proximal spawning cues, although the timing of spawning varied on a number of spatial and temporal scales. Major spawnings coincided with sharp drops in sea-surface temperature associated with wind-driven upwelling. Temperature change could be a distinctive inducer to synchronize spawning among individuals, and may result in gametes being expelled into water masses favorable for fertilization and larval development.

COOPERATION OF SHELLFISH GROWERS AND BIOLOGISTS IN DETECTING AND MONITORING INVASIVE SPECIES: THE EUROPEAN GREEN CRAB INVASION IN OREGON. Sylvia Behrens Yamada*, Zoology Department, Oregon State University, Corvallis, Oregon 97331-2914. E-mail: yamadass@science.oregonstate.edu

The recent invasion of Pacific Northwest estuaries by the European green crab, *Carcinus maenas*, initially caused much alarm. Following the strong El Niño of 1997–98, young green crabs appeared in estuaries along the coasts of Oregon, Washington, and as far north as Nootka Sound on the west coast of Vancouver Island, British Columbia. Heath Hampel, a shellfish grower, in Coos Bay, Oregon played a critical role in alerting biologists in this invasion, thus allowing us to document and interpret the invasion process. Unusually strong northward-moving coastal currents of up to 50 km/day during strong El Niño events correlated with good recruitment and northward range expansions of green crabs. It thus appears that these currents transported larvae from more established populations in California to Northwest estuaries. Since the last El Niño, coastal transport events have been much weaker and green crab recruitment much lower.

Shellfish growers and sports crab harvesters in Oregon and Washington also help biologists determine the age structure of the green crab population by taking their captured green crabs to extension offices. From carapace width and condition biologists can estimate age. For example, in the summer of 2003, we saw large individuals from the strong 1997–1998 year class decrease in numbers and smaller, younger crabs taking their place.

While green crab abundance in the Northwest is still low, it is imperative to continue monitoring efforts to elucidate the process of range expansion of this non-indigenous marine species and to serve as an early warning system for the next strong recruitment event. However, as the novelty of a marine invader wears off and densities remain low, funding sources for studying the invasion dry up. As this happens, the role of shellfish growers and crab harvesters in reporting non-indigenous species sightings to biologists becomes increasingly important.

THE FARMING OF AND PEARL CULTIVATING FROM WING OYSTER *PTERIA PENGUIN* IN SOUTHERN CHINA. X. Y. Yu, M. F. Wang, F. L. Liang, and Y. Liu, Pearl Research Institute, Zhanjiang Ocean University, Zhanjiang 524025, China; X. Y. Yu, and J. F. Gui, Institute of Hydrobiology, Chinese Academy of Sciences, Wuhan 430072, China. E-mail: yuxyong@163.net

The wing oyster *Pteria penguin* distributed along the coast of Hainan Island, Leizhou Peninsula and other maritime regions in Southern China Sea. It is a kind of large-sized and fast grow-

ing bivalve species. The trial farming of and pearl cultivating from this species were conducted about 5 years ago. At first, natural shells were captured mainly for half-sphered pearl (mabe) culturing, then the matured wild individuals were chosen as parents for seed producing. After a serial of trials, the procedures of the stock shells selecting and cultivating, inducing spawning, larval rearing, spat collecting, and nursing out and fostering them to matured adult was successfully developed. In this disquisition, the whole procedure from zygote to adult was depicted.

Sufficiently proliferation primarily from the wild shells and then from farmed stocks provided enough oysters for trials of pearl producing. Cooperated with our research group, two companies in Hainan Island and one in Leizhou Peninsula have developed technology of producing mabe profitably. Recently, round pearls yielded successfully from this species. Cultivation of half-sphered and round pearl from wing oyster also described generally.

GENETIC ANALYSIS OF SELECTED STRAINS OF THE EASTERN OYSTER (*CRASSOSTREA VIRGINICA* GME-LIN) USING AFLP AND MICROSATELLITE MARKER S. Ziniu Yu and Ximing Guo, Haskin Shellfish Research Laboratory, Institute of Marine and Coastal Sciences, Rutgers University, Port Norris, NJ 08349, USA. E-mail: carlzyu@hsrl.rutgers.edu

Amplified fragment length polymorphisms (AFLPs) and microsatellite markers were used to examine genetic variation and divergence among four selected strains (DBH, NEH, FMF, and CTS) and one wild population (DBW) of the eastern oyster, *Crassostrea virginica* Gmelin. Eighty-six AFLP markers (from three primer sets) and five microsatellite loci were used for the analysis of 30 oysters from each of the five populations. Microsatellites were considerably more variable than AFLPs. Observed heterozygosities ranged from 0.560–0.640 across the populations for microsatellites, and from 0.186–0.207 for AFLPs. Microsatellites detected more genetic variation per locus, whereas AFLPs were more efficient at generating informative loci. Both pairwise F_{st} and Φ_{PT} analysis of microsatellite data and pairwise Φ_{PT} analysis of AFLP data revealed significant genetic differentiation between all pairs of populations. There was no significant reduction in heterozygosity in all four selected strains compared with the wild population. However, the number of alleles per locus (N_a) for microsatellites was lower in the selected strains than that in the wild population, mostly due to the losses of rare alleles. Two strains subjected to long-term selection for disease-resistance showed consistently increased frequencies at a few AFLP loci, which deserve further analysis to determine if they are linked to disease-resistance genes.

THE NATIONAL SHELLFISHERIES ASSOCIATION

The National Shellfisheries Association (NSA) is an international organization of scientists, management officials and members of industry that is deeply concerned and dedicated to the formulation of ideas and promotion of knowledge pertinent to the biology, ecology, production, economics and management of shellfish resources. The Association has a membership of more than 1000 from all parts of the USA, Canada and 18 other nations; the Association strongly encourages graduate students' membership and participation.

WHAT DOES IT DO?

- Sponsors an annual scientific conference.
- Publishes the peer-reviewed *Journal of Shellfish Research*.
- Produces a Quarterly Newsletter.
- Interacts with other associations and industry.

WHAT CAN IT DO FOR YOU?

- You will meet kindred scientists, managers and industry officials at annual meetings.
- You will get peer review through presentation of papers at the annual meeting.
- If you are young, you will benefit from the experience of your elders.
- If you are an elder, you will be rejuvenated by the fresh ideas of youth.
- If you are a student, you will make useful contacts for your job search.
- If you are a potential employer, you will meet promising young people.
- You will receive a scientific journal containing important research articles.
- You will receive a Quarterly Newsletter providing information on the Association and its activities, a book review section, information on other societies and their meetings, a job placement section, etc.

HOW TO JOIN

- Fill out and mail a copy of the application blank below. The dues are 65 US \$ per year (\$35 for students) and that includes the *Journal* and the Newsletter!

NATIONAL SHELLFISHERIES ASSOCIATION—APPLICATION FOR MEMBERSHIP
(NEW MEMBERS ONLY)

Name: _____ For the calendar year: _____ Date: _____

Mailing address: _____

Institutional affiliation, if any: _____

Shellfishery interests: _____

Regular or student membership: _____

Student members only—advisor's signature REQUIRED: _____

Make checks (*MUST* be drawn on a US bank), international postal money orders or VISA for \$70 (\$35 for students with advisor's signature) payable to the National Shellfisheries Association and send to Nancy Lewis, Bookkeeper, PO Box 350, V.I.M.S. Eastern Shore Lab, Wachapreague, VA 23480, USA.

INFORMATION FOR CONTRIBUTORS TO THE JOURNAL OF SHELLFISH RESEARCH

Original articles dealing with all aspects of shellfish research will be considered for publication. Manuscripts will be judged by the editors or other competent reviewers, or both, on the basis of originality, content, merit, clarity of presentation, and interpretations. Each article should be carefully prepared in the style followed in prior issues of the *Journal of Shellfish Research* before submission to the Editor. Papers published or to be published in other journals are not acceptable.

Title, Short Title, Key Words, Abstract: The title of the paper should be kept as short as possible. Please include a "short running title" of not more than 48 characters including spaces, and key words. Each manuscript must be accompanied by a concise, informative abstract, giving the main results of the research reported. The abstract will be published at the beginning of the article. No separate summary should be included.

Text: Manuscripts must be typed double-spaced throughout on one side of the paper, leaving ample margins, with the pages numbered consecutively. Scientific names of species should be underlined or in italics and, when first mentioned in the text, should be followed by the authority. Common and scientific names of organisms should be in accordance with American Fisheries Society Special Publications 16 and 17: *Common and Scientific Names of Aquatic Invertebrates from the United States and Canada: Mollusks and CSNAIUSC: Decapod Crustaceans*, or relevant publications for other geographic regions.

Abbreviations, Style, Numbers: Authors should follow the style recommended by the sixth edition (1994) of the *Council of Biology Editors [CBE] Style Manual*, distributed by the American Institute of Biological Sciences. All linear measurements, weights, and volumes should be given in metric units.

Tables: Tables, numbered in Arabic, should be on separate pages with a concise title at the top.

Illustrations: Line drawings should be in black ink or laser print and planned so that important details will be clear after reduction to page size or less. No drawing should be so large that it must be reduced to less than one third of its original size. Photographs and line drawings should be prepared so they can be reduced to a size no greater than 17.3 cm × 22.7 cm, and should be planned either to occupy the full width of 17.3 cm or the width of one column, 8.4 cm. Photographs should be glossy with good contrast and should be prepared so they can be reproduced without reduction. Originals of graphic materials (i.e., line drawings) are preferred and will be returned to the author. Each illustration should have the author's name, short paper title, and figure number on the back. Figure legends should be typed on separate sheets and numbered in Arabic.

Digital Figures: Authors may provide digital figures (they are not required); they must be accompanied by hardcopy figures of equal quality, which the printer will use for comparison and backup. If digital figures are supplied, please note the following instructions:

- Each piece of art should be saved as its own file.
- Files must be one of the following formats: TIF, EPS, or JPG.
- Each file should be named according to its figure number and format (e.g., "fig2b.tif").

- Figures must not be embedded in a word-processor or spreadsheet document: the printer cannot use images stored in Word, WordPerfect, Excel, Powerpoint, etc.
- Resolution: *line shots*: 1000 dpi; *halftones/grayscale*: 300 dpi if no lettering, 500 dpi if figure contains lettering.
- Color figures: save the files as CMYK-encoded TIF images (preferred) or CMYK-encoded EPS or JPG images. Color figures have the same resolution requirements a B/W, above. Color illustrations will not be accepted unless the author agrees to cover the cost of associated reproduction and printing.

Literature Cited: References should be listed alphabetically at the end of the article. Abbreviations in this section should be those recommended in the *American Standard for Periodical Title Abbreviations*, available through the American National Standard Institute, 1430 Broadway, New York, NY 10018. For appropriate citation format, see examples below:

ANTIMICROBIAL ACTIVITY OF COPPER AND ZINC ACCUMULATED IN EASTERN OYSTER AMEBOCYTES

WILLIAM S. FISHER

United States Environmental Protection Agency, Office of Research and Development, National Health and Environmental Effects Research Laboratory, Gulf Ecology Division, 1 Sabine Island Drive, Gulf Breeze, FL 32561

ABSTRACT The distribution of eastern oysters *Crassostrea virginica* near terrestrial watersheds has led to a general impression that low or variable salinity is imperative for survival. However, freshwater runoff contains numerous mineral elements from geologic deposits that could play significant roles in oyster physiology. Two metals of terrestrial origin, copper and zinc, are accumulated to extremely high concentrations in eastern oysters, even in the absence of anthropogenic sources. As yet, there has been no defensible demonstration of a physiologic function for such high concentrations. Both copper and zinc, however, are accumulated almost exclusively in the amebocytes and calcareous shell of oysters, a unique distribution that implicates a role in the functions of amebocytes. Amebocytes are migratory, diapedetic cells generally recognized to provide nutriment and defense through phagocytosis, killing, and digestion of invading or ingested microorganisms. There is sufficient evidence in existing literature to suggest that copper and zinc directly contribute to these antimicrobial activities. This review presents historical and recent findings that demonstrate a strong affinity of oyster amebocytes for copper and zinc (even in low ambient concentrations), prolonged retention of the metals despite a potential route of elimination, and strong circumstantial evidence of antimicrobial activity by accumulated copper and zinc. It is proposed that oysters actively concentrate copper and zinc as antimicrobial agents to be used in intracellular and extracellular killing (direct toxicity) as well as extracellular clot formation (precipitation of hemolymph). This potential, combined with evidence of amebocyte involvement in deposition of oyster shell, provides an alternative framework for understanding amebocyte functions, defense activities, and coastal distributions of oyster populations. It also affords some resolution to the apparent contradiction of eastern oysters thriving at seemingly polluted locations.

KEY WORDS: oysters, *Crassostrea virginica*, marine bivalves, copper, zinc, metals, contaminants, amebocytes, leucocytes, hemocytes, internal defense, immunomodulation, immunosuppression, metal toxicity, sentinel species

INTRODUCTION

Eastern oysters *Crassostrea virginica* are distributed across the North American coast of the Atlantic Ocean and Gulf of Mexico in bays, estuaries, and coastal zones, most often near sources of fresh water. The proximity to fresh water has often led to a conclusion that oysters require the low or variable salinity provided by freshwater inflow (Cake 1983, Soniat & Brody 1988, Berrigan et al. 1991). Intermittent salinity reductions can deter stenohaline predators such as oyster drills (Loosanoff 1955, Lunz 1955, Hopkins 1956, Wells 1961, Menzel et al. 1966, Berrigan et al. 1991) and can slow incidence of disease caused by the protozoans *Perkinsus marinus* and *Haplosporidium nelsoni* (Sprague et al. 1969, Ford 1985, Ford & Haskin 1988, Chu & Greene 1989, Chu et al. 1993, La Peyre et al. 2003). However, there is ample evidence of near-shore, intertidal oyster beds in high-salinity estuaries and coastal zones (Beaven 1955, Gunter & Geyer 1955, Lunz 1955, Nelson 1955, Copeland & Hoese 1966). It is possible then, that eastern oysters are influenced by other factors that accompany freshwater influx, such as terrestrial elements, rather than reduced salinity. Copper and zinc, like many elements in the marine environment, originate from natural terrestrial sources and are delivered to oyster beds in watershed runoff (Prytherch 1934, O'Connor 2002). Runoff with sufficient volume (i.e., streams and rivers) can generate flows that bring elements far and deep into the receiving water where subtidal oyster beds exist. Without such runoff, oysters may be confined to shallow intertidal areas adjacent to land where the elements originate. If this is correct, the availability of terrestrial elements may well be a principal determinant in the distribution of eastern oysters.

Copper and zinc are terrestrial elements of special interest because they accumulate to extraordinary concentrations in eastern oysters. They are accumulated against chemical gradients, even from low ambient concentrations, and are retained within the oyster longer than other metals, despite the apparent availability of an elimination mechanism. Moreover, zinc and copper are exclusively sequestered in oyster amebocytes (Fig. 1). This brings them into direct contact with a cell type credited with many indispensable responsibilities for oyster survival, including antimicrobial activities for defense and nutrition. These considerations implicate a physiologic reliance on copper and zinc that, if true, would support the concept that terrestrial elements are key factors in oyster success and distribution. Furthermore, it would resolve the apparent contradiction that eastern oysters often thrive at relatively polluted locations (e.g., Abbe & Sanders 1986). Fortunately, there is ample information in the literature to examine such a possibility. Because of the highly accumulated concentrations and unique association with amebocytes, uptake and disposition of copper and zinc in oysters has been widely studied.

Throughout the literature a perception exists that high concentrations of metals, copper in particular, are harmful to oysters. Yet evidence for such a perception is lacking, at least for adult eastern oysters. In fact, the highest known tissue concentrations of copper and zinc for any marine organism are found in tissues of apparently healthy eastern oyster adults. The perception of harm originates from the knowledge that such high concentrations would be quite toxic to most other biota. Yet, eastern oysters not only survive high ambient concentrations of copper and zinc, but avidly recruit the metals and accumulate them without ill effect. Several studies have shown that concentrations in oyster tissues are much higher than in the ambient environment, and that oysters assimilate and retain copper and zinc from environments with low ambient

Figure 1. Amebocytes of eastern oysters *Crassostrea virginica* consist of granular and agranular cells capable of movement throughout the hemolymph, tissues, and mantle cavity of the organism. The ability to traverse epithelial layers is called diapadesis. Amebocytes shown here were withdrawn with hemolymph plasma from the adductor muscle and allowed to settle in seawater in a glass dish. Amebocytes form aggregates (clumps of cells) upon withdrawal, but eventually begin to move away from the aggregates using ameboid locomotion.

concentrations. The latter refutes any suspicion that eastern oysters passively, or inadvertently, absorb metals or that they accumulate metals only when exposed to polluted environments. If we accept that successful organisms do not expend energy without purpose, then active uptake and storage implies that oysters must accumulate copper and zinc for a physiologic purpose.

The literature is reviewed here to characterize evidence that supports a physiologic function for copper and zinc as antimicrobial agents in amebocytes. High concentrations are likely required to provide an expansive and flexible defensive and nutritional capability. More specifically, it is hypothesized that they serve as precipitating agents in extracellular clotting and as toxic antimicrobial agents for both extracellular wound protection and intracellular phagocytic activity. It is further speculated that copper, zinc, and possibly other terrestrially derived elements are essential precipitating agents for adult shell deposition (Fisher 2004). Dependence of these activities on copper may have co-evolved with the apparently exclusive requirement for this metal in eastern oyster setting and metamorphosis (Prytherch 1934). Because of these dependencies, availability of copper and other terrestrially derived metals have a major influence on the success and distribution of eastern oysters.

There are several topics relevant to this proposal and an abundance of evidence to consider. A historical perspective (Section I) summarizes early observations of copper and zinc accumulation in oysters, including emergence of a perception that high concentrations of copper are abnormal and toxic to oysters. Section II reviews the close association of copper and zinc with amebocytes, including their exclusive storage in amebocyte granules and positive association with amebocyte numbers. Section III introduces evidence of avid and non-toxic uptake and retention of copper and zinc in granules of eastern oyster amebocytes. Field studies summarized in Section IV demonstrated greater amebocyte numbers and antimicrobial activity for oysters with high tissue concentrations of copper and zinc. In Section V, data are presented that

support a role for copper and zinc in oyster defense activities. Finally, in Section VI, a series of umbrella hypotheses are presented that generate an alternative framework for interpreting high concentrations of copper and zinc, amebocyte activities in nutrition and defense, and the role of terrestrial metals in coastal distributions of eastern oyster populations.

EARLY STUDIES OF COPPER AND ZINC IN OYSTERS

Eastern oysters, once called American oysters, inhabit the coastline along the Atlantic and northern Gulf of Mexico in North America. Scientific names for this estuarine and near-coastal species have included *Ostrea virginiana* (or sometimes *O. virginica*), *Gryphaea virginica*, and the current *Crassostrea virginica*. Although a subsistence food for Native Americans and early colonials, eastern oysters did not represent a substantial commercial interest until the late 19th century (Hargis & Haven 1999). As popular consumption increased, food safety issues grew within the industry. Bacterial and chemical impurities were recognized to cause illness in consumers and, as today, cases of poisoning greatly influenced success in the market.

Green Oysters and Suspected Copper Toxicity

One such chemical impurity was copper. The occasional occurrence of a blue-green tint to oyster meats fueled fears of copper contamination from mines or copper-painted ship bottoms. Oyster tissues resembled the color of copper-salt residues found on cooking vessels (Fig. 2, left). Concerns over green oysters in North America were amplified by the lack of scientific agreement in Europe, where the European flat oyster *Ostrea edulis* had long been a culinary staple. Some asserted that high concentrations of copper were responsible for green *O. edulis* (e.g., Bizio 1845, Thorpe 1896), whereas others believed green color was simply a pigment acquired from ingested food (Gaillon 1824, Thiselton Dyer 1877). The latter group maintained that *O. edulis* raised in holding ponds (*claires*) near the Marennes region of France acquired a green tinge along the gill filaments (see Fig. 2, right) from a diatom *Navicula ostrearia*, which grew in the ponds. The green oysters from Marennes were a highly regarded cuisine.

It is peculiar that a green oyster controversy even existed because O'Shaughnessy (1866) had earlier resolved the conflicting

Figure 2. Green-tinted oysters. Left: Eastern oyster *Crassostrea virginica* colored on surfaces of soft tissues by high concentrations of copper in amebocytes. Right: European flat oyster *Ostrea edulis* dyed in the gills by pigment from diatoms (*Navicula ostrearia*). (Drawings reproduced from Herdman & Boyce 1899 in the Lancashire Sea-Fisheries Memoir No. I, Plate VI, Fig 6, and Plate IV, Fig. 6, respectively).

evidence. He related the trial of a tradesman who, "actuated by the lawless desire of premature aggrandizement", was found guilty of selling copper-laden oysters that sickened consumers. The tradesman was unable to obtain green oysters from Marennes, so instead collected substitutes from the outfall of a copper mine in Cornwall, England. O'Shaughnessy (1866) concluded that both diatoms and copper could elicit greenness in oysters. Nonetheless, subsequent investigators in both Europe and America continued to dispute the issue. Some of the dissension is worth recounting because it has fashioned, in part, an existing predisposition that copper is a toxic element for oysters.

Sensitive to the controversy in Europe, John A. Ryder of the Smithsonian Institution reported to the United States Fish Commission that green color in American oysters was most likely a pigment from ingestion of sea cabbage (*Ulva latissima*) or a diatom similar to *Navicula ostrearia* (Ryder 1882). Much of Ryder's conviction however, appears to be based on a notion that oysters could not possibly survive the high concentrations of copper it would take to turn them green.

"That it is not copper we may be equally certain, for any such quantity of a copper salt as would produce the green gills and patches on the mantle, such as are often observed, would without doubt be as fatally poisonous to the oyster as to a human being." (Ryder 1882, p. 410)

Green oysters were tested at two independent laboratories, both substantiating Ryder's claim; there was no evidence of copper in the green portions of tissue. Ryder saw that the green color was actually confined to independent cells that moved freely about the mantle and gills. By virtue of their amebiform ability to migrate, he proposed that these 'blood cells' could enter the digestive tract and absorb green pigment from intestinal juices. But, in spite of his findings, Ryder remained convinced that any oyster with green tissues must be diseased.

Most of Ryder's observations were independently confirmed in studies by Professor E. Ray Lankester (University College, London), who dismissed all reports of copper, at least in those green *O. edulis* that he examined from Europe (Lankester 1886). He strongly believed that green coloration, which he called "marenin", was imparted solely from ingestion of *Navicula*. Like Ryder, Lankester noted that the color was confined to certain "secretion cells" in the gill epithelium. He was puzzled by the ability of these specialized epithelial cells to independently migrate across gill surfaces. Neither Ryder (1882) nor Lankester (1886) were privy to the pioneering insights on invertebrate amoebocytes later summarized by Elie Metchnikoff (1891).

Dr. Thorne Thorpe (1896) determined that "green-bearded" or "green-finned" oysters from Marennes were so-colored from the diatom *Navicula*, and he found that copper quantities in these oysters were sometimes far less than found in "normal" white oysters. Nonetheless, he accepted O'Shaughnessy's contention that greenness could also originate from copper:

"But there is no question that the greenness of certain oysters, especially those found in Falmouth and Truro waters, is due to copper. The color, both in character and distribution, is, however, quite different from that of the Marennes oyster. The green Cornish oyster is unsaleable in this country—at least for immediate consumption—as it leaves a distinct metallic taste in the mouth, similar, it is said, to that due to 'sucking a penny'." (Thorpe 1896, p. 107)

The color, metallic taste and copper content of green oysters gradually dissipated to "normal levels", Thorpe found, with their

transfer to cleaner water. These normal concentrations were judged to be more appropriate for accepted physiologic functions, in particular as a component of the respiratory pigment hemocyanin, which at the time had been described in the blood of octopus and other molluscs (Thorpe 1896).

Professor W. A. Herdman (1896) believed the green tint he observed on experimental *O. edulis* and *O. virginica* was a sign of disease. He ran chemical tests on these oysters and, at first, concluded unequivocally that "copper had nothing to do with the disease" (p. 164). Only 1 year later, however, he reversed his stance to accept the views of O'Shaughnessy and Thorpe.

"There are evidently several kinds of greenness in oysters, and whereas some may be due to normal and healthy processes, others must be regarded as abnormal or diseased conditions. It is the latter, in our experience, that contain the copper." (Boyce & Herdman 1897, p. 31)

Boyce and Herdman (1897) described experiments with *O. virginica* transplanted to Fleetwood, England. They found American oysters had a different shade of green and much higher concentrations of copper than any of the English, Dutch, or Marennes oysters (*O. edulis*), except for occasional green specimens from Falmouth. They recounted several findings: (1) green oysters contained up to four times the copper of white oysters; (2) green tissues contained more copper than white tissues; (3) green coloration was strongly associated with the distribution of green amoebocytes (described as ameboid, wandering leukocytes, Fig. 3); and (4) copper was exclusively associated with the green amoebocytes. The blue-green tint of the American oysters, they surmised, was due to copper-laden amoebocytes that migrated into the mantle cavity and onto the external surfaces of the tissues. They also found tinted amoebocyte aggregates in the heart and sinus vessels (Fig. 4), as well as among the connective and epithelial tissues. These findings remain undisputed.

Boyce and Herdman (1897), like Ryder (1882), felt that copper-laden green oysters were diseased. They suggested that copper accumulation in amoebocytes was

"... due to a disturbed metabolism, whereby the normal copper of the haemocyanin, which is probably passing through the body in minute amounts, ceases to be removed, and so becomes stored up in certain cells." (Boyce & Herdman 1897, p. 38)

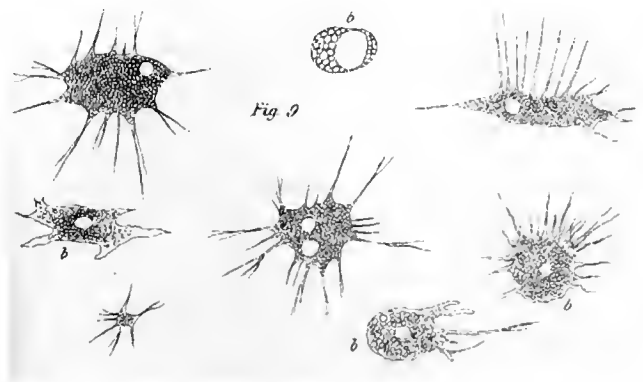

Figure 3. Drawings of large amoeboid "leukocytes" found on the surface of gill and mantle of green *Crassostrea virginica*. The presence of granules is evident in the drawings. "b" denotes cells from the blood (hemolymph). (Reproduced from Herdman & Boyce 1899; Plate V, Fig. 9).

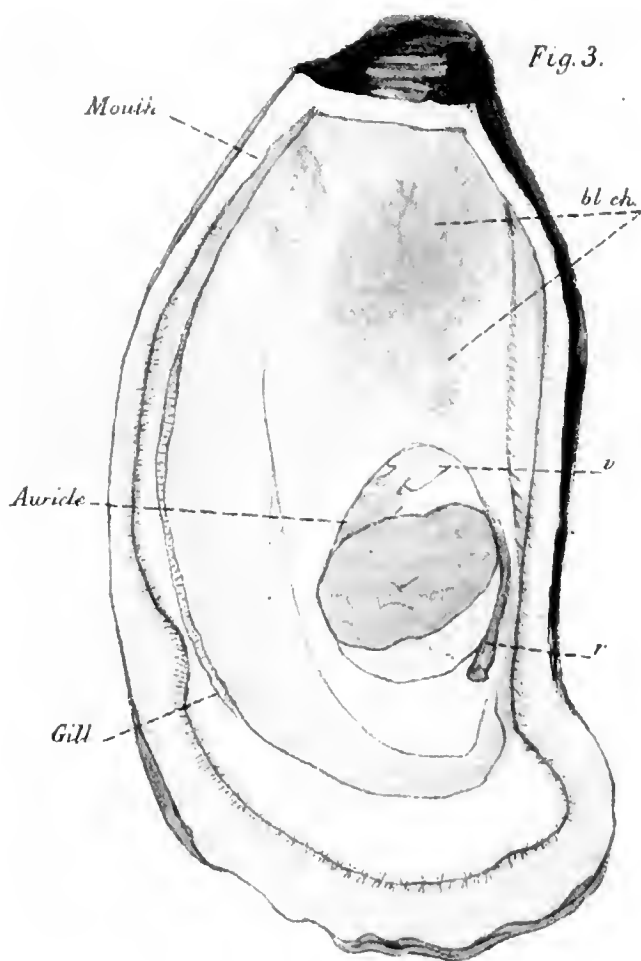

Figure 4. Green-tinted *Crassostrea virginica* showing blood channels (bl. ch.) and auricles of the heart engorged with green amoebocytes. The letter v denotes ventricle and r denotes rectum. (Reproduced from Herdman & Boyce 1899; Plate VI, Fig. 3).

They described a degenerative reaction in green oysters, a striking increase in amoebocytes that collected in clumps and abnormally distended the blood vessels (see Fig. 4). Their evidence was eventually published in an often-cited treatise (Herdman and Boyce 1899) that clearly distinguished "diseased" American and Falmouth oysters, stained with high concentrations of copper, from the healthy Marennes and Roach River oysters tinted by pigments from diatoms. In their definitive work, Herdman and Boyce (1899) detailed the location and severity of both types of green discoloration with color drawings (see Figs. 2–4), quantified concentrations of copper and iron in oysters from several sources, and reported limited success in staining oysters green through exposure to high concentrations of soluble copper oxide and copper chloride.

In spite of a long history and plentiful evidence, controversy over the role of copper in green oysters persisted into the 20th century (Pease 1911, Nelson 1916 [cited from Hunter & Harrison 1928], Ranson 1924, Ranson 1925, Yonge 1928, Galtsoff & Whipple 1930, Takatsuki 1934). Some confusion may have been due to the fact that a green tint is most easily seen when amoebocytes are present on the surface of the tissues, a condition that may vary for reasons unrelated to copper accumulation. For eastern oysters, the controversy was seemingly resolved when Galtsoff and Whipple (1930) found green oysters from New Haven Harbor

(Long Island Sound) to contain copper at concentrations of 1,217–2,719 $\mu\text{g g}^{-1}$ (dry weight) compared with only 82–138 $\mu\text{g g}^{-1}$ in white oysters from Onset Bay (MA). There is now a general acceptance that copper can accumulate in amoebocytes to concentrations high enough to impart green coloration. In fact, Galtsoff (1964) noted that,

"In the case of pronounced green discoloration the presence of metallic copper may be demonstrated by inserting in the tissues a well-polished steel knife; the surface becomes copper plated in a short time. This simple method can be used profitably for a qualitative demonstration of the presence of copper." (Galtsoff 1964, p. 388)

There is no longer any doubt that copper at high concentrations in eastern oysters will create greenish coloration. Abbe and Sanders (1986) predicted that concentrations of copper must be more than 700 $\mu\text{g g}^{-1}$ (dry) for oysters to turn green, and that all oysters would be green at 2,000 $\mu\text{g g}^{-1}$. Along with this acceptance is the unmistakable perception that such high accumulations are abnormal, are a direct consequence of environmental pollution, and are responsible for a toxic or diseased reaction in oysters.

One additional study on the association of copper with eastern oysters is particularly significant. In both field and laboratory studies, Prytherch (1934) found copper was required for setting and metamorphosis of eastern oyster larvae. In studies at Milford, Connecticut, he found larvae would not set if copper was excluded from the seawater. He further showed that by removing copper from the seawater immediately after setting, metamorphosis would cease until its re-addition. Prytherch (1934) cemented oyster larvae to glass dishes to microscopically examine and chronicle morphologic changes during metamorphosis. He observed that larval pigment spots (more often called 'eye spots') were composed of about 300 aggregated, immobile amoebocytes. Addition of copper to the seawater initiated movement of the pigment spot amoebocytes and their inaugural migration into the bloodstream. Although important to this review and pivotal to the argument for amoebocyte participation in shell deposition (Fisher 2004), these findings have been generally overlooked in the literature and have never been validated.

High Zinc Accumulation and Radioactive ^{65}Zn from Nuclear Reactors

The earliest reports of zinc accumulation by eastern oysters stemmed from broad-based efforts to determine whether all living organisms contained zinc and, if so, what physiologic purpose the element might serve. Two early contributions (Bradley 1904, Mendel & Bradley 1905) revealed that concentrations of zinc oxide in the hepatopancreas of *Sycotypus canaliculatus*, a large carnivorous gastropod, were well above 10%. They found only negative or "doubtful" concentrations for a variety of other New England marine crustaceans and molluscs, including *O. virginiana*. Mendel and Bradley (1905), based on existing knowledge that many invertebrates contained copper in the respiratory pigment, suggested zinc might bind to an analogous respiratory pigment. Although it was never characterized, they named this presumptive pigment 'hemocytopyin' (Mendel & Bradley 1906, Mendel & Bradley 1907). Zinc was found in the tissues of several marine organisms from the Tortugas by Phillips (1917; Table 1), who concluded it must be a natural constituent because the Tortugas were far removed from anthropogenic influences (although some samples were collected from the moat at Fort Jefferson). This approach, surveying fauna to generate hypotheses of potential function, reached a pinnacle in the work of Vinogradov (1953), who examined metal content in several marine phyla.

TABLE 1.

Concentrations of copper and zinc oxide detected in various marine species from the Dry Tortugas as reported by Phillips (1917). Values were recalculated from analytical results obtained with 20 g dry tissue. Copper was determined electrolytically in nitric acid solution. Zinc was precipitated as a sulphide in acetic acid solution and weighed as ZnO. Other analytes measured by Phillips (1917) include Fe, MnO, and PbO₂.

Many early observations on zinc in oysters were focused on the high concentrations that were accumulated. Hiltner and Wichmann (1919) found zinc and copper accumulated to high concentrations in Atlantic coast eastern oysters; they believed the elements were accumulated from the food chain because concentrations were so much greater than for seawater.

"There appears, moreover, to be no direct, uniform ratio between the quantity of copper and zinc in oysters and the amount in the seawater in which they are found, although it is true, in general, that oysters contain larger proportions of the metals when grown in seawater highly contaminated with metallic wastes from smelters and other factories." (Hiltner & Wichmann 1919, p. 217)

Although they noted a potential role for zinc in respiration, Hiltner and Wichmann (1919) attributed no biologic significance to these exceptionally high concentrations. In fact, they concluded that the concentrations seemed too great to even consider a functional role.

Bodansky (1920) examined 20 different marine species from the Gulf of Mexico for accumulation of zinc and found the concentrations in eastern oysters extraordinary. It was, he suggested,

"... a striking phenomenon that the oyster living in a water, not contaminated by industrial wastes, should contain in its tissues more than 35,000 times as much zinc as is present in an equivalent weight of water." (Bodansky 1920, p. 403)

Bodansky (1920) also concluded that the source of zinc was probably oyster food, and he believed that zinc might play a role in respiration. Based on chemical analyses of dissected oyster tissues, he reported that zinc was distributed evenly in the digestive organ, mantle, and gills, yet was considerably lower in the adductor muscle.

Investigations into zinc accumulation by oysters gained significance in the mid-1950s as coastal zones and estuaries were exposed to increasing levels of industrial waste as well as radioactive contamination from nuclear reactors, fuel reprocessing plants, and fallout from intensive nuclear weapons testing. In a study to characterize the radioactive pollution from a nuclear power station in Essex, England, Preston (1968) examined ¹³⁷Cs, ⁶⁰Co, ⁵⁵Fe, and ⁶⁵Zn in the receiving estuary and found that ⁶⁵Zn was the only nuclide appreciably assimilated by oysters. The amount accumulated was proportional to the exposure, as demonstrated by diminishing concentrations of ⁶⁵Zn as oyster collections moved further from the source (Table 2). Because of this capacity to accumulate ⁶⁵Zn and a link with human food consumption, oysters were considered an ideal indicator organism to assess food-borne risk (Murthy et al. 1959, Fitzgerald & Skauen 1963, Wolfe 1970a, Romeril 1971). In general, these reports showed that oysters near radioactive effluents accumulated ⁶⁵Zn at levels too low to affect human health; reports describing effects on oysters have not been found.

Impetus for food safety led to advances in radioactive tracing technology. Methods were developed to track the differential uptake of ⁶⁵Zn by aquatic species and its passage through biogeochemical cycles (Chipman et al. 1958, Watson et al. 1961, Alexander & Rowland 1966, Duke 1967). In one such study, Chipman et al. (1958) showed that clams, scallops, and particularly oysters (*C. virginica*) accumulated zinc thousands of times higher than seawater. Using radioactive ⁶⁵Zn, they found uptake and exchange of zinc between the seawater and tissues to be rapid and in continuous flux. They also noted a considerable amount of ⁶⁵Zn in oyster shells, which they attributed to adsorption because of the dynamic uptake and exchange. Their studies included measurement of uptake by excised oyster gill sections, influences of chelating agents, and tissue distributions of injected ⁶⁵Zn. They attempted to extract ⁶⁵Zn from oyster tissues and found that about half the zinc was extractable by water alone.

Wolfe (1970a) described studies on *C. virginica* from North Carolina that used both stable and isotopic zinc. He found that soft tissues contained about six times the zinc concentration of shells, but because the shells were so heavy they contained nearly 45% of the total zinc in an oyster. Similar to Bodansky (1920), Wolfe found that tissues with large external surface areas (gills, mantle,

TABLE 2.

The amount of ⁶⁵Zn in *O. edulis* tissues decreased with distance from the source, a cooling water outfall from a nuclear generator in Essex, England, as reported by Preston (1966).

Distance from Outfall (Statute Miles)	[⁶⁵ Zn] (pCi/g)
0.33	100
1.0	42
2.0	33
2.75	19
5.75	9.1

labial palps, gonad, and digestive gland) had higher concentrations of zinc than other tissues (adductor muscle, pericardial sac). Romeril (1971) demonstrated that *C. angulata* (Portuguese oysters) accumulated ^{65}Zn to higher concentrations than *O. edulis*, but found similar tissue distributions. This fact, he believed, indicated a common uptake mechanism among oyster species. Romeril (1971) found a high concentration of ^{65}Zn with the shell, as had previous investigators (Chipman et al. 1958, Fitzgerald & Skauen 1963, Wolfe 1970a), but showed that co-incubation with iron or cobalt would reduce this ^{65}Zn concentration, presumably due to binding-site competition. This finding supported his conclusion that zinc was adsorbed to the shell and in constant flux.

Few hypotheses on a potential role for such high concentrations of accumulated zinc emerged from these studies. It was clear, since the study of Bodansky (1920), that some zinc was bound to protein and might serve as enzyme co-factors; but calculations by Pequegnat et al. (1969) indicated that accumulation was much greater than any known or speculated requirements. Potential roles for zinc in enzyme activation have been investigated: Zinc-dependent enzymes in *C. virginica* include carbonic anhydrase, alkaline phosphatase and malic dehydrogenase (Wolfe 1970b), and in *O. edulis* they include carbonic anhydrase, alkaline phosphatase, carboxypeptidase A, and α -D-mannosidase (Coombs 1972). However, in both cases the investigators concluded that accumulated zinc was far in excess of enzymatic zinc requirements. This inconsistency between requirement and accumulated concentrations led Wolfe (1970a) to suggest,

"The accumulation of zinc and other trace metals may be partly a coincidental result of poor discrimination by the biologic mechanism for calcium uptake and shell deposition. This possibility is consistent with the observed seasonality of trace element concentration ... where contents of manganese, iron, copper, and zinc were higher during warm months when shell deposition is greatest." (Wolfe 1970a, p. 55)

Considering the great interest that many early investigators placed on a role for copper and zinc in oyster physiology, the lack of ensuing studies is remarkable. This dwindling attention may have risen from a sense that such extraordinarily high concentrations precluded any possible physiologic purpose.

METAL ACCUMULATION IN OYSTER AMEBOCYTES

Ostensibly, eastern oysters flourish in shallow coastal areas and estuaries because freshwater inflow creates reduced or variable salinities that thwart marine predators (e.g., oyster drills; Wells 1961, Menzel et al. 1966) and marine pathogens such as the protozoans *Perkinsus marinus* (Andrews & Ray 1988) and *Haplosporidium nelsoni* (Ford & Haskin 1988). Yet, freshwater inflow also transports terrestrial elements, including both natural and anthropogenic metals, from the watershed. Any dependence by oysters on terrestrial metals must have evolved from natural geologic sources because anthropogenic sources are relatively recent. Nonetheless, the two sources are sometimes confounded. Both metals and polycyclic aromatic hydrocarbons (PAH), even though they are naturally derived, are often associated with human activities because their levels are elevated in urban and industrial discharge (Hiltner & Wichmann 1919, Hunter & Harrison 1928, Chipman et al. 1958, Galtsoff 1964, Pringle et al. 1968, Roosenburg 1969, Boyden & Romeril 1974, O'Connor 2002). Elevated concentrations of metals and PAH, along with wholly anthropogenic polychlorinated biphenyls (PCB) and pesticides, are usually

considered indicators of environmental pollution. Although there are natural sources for metals, a perception persists that certain metals, including copper and zinc, are environmental contaminants with a potential for toxic, detrimental effects on human health and the condition of flora and fauna.

Bivalves as Sentinels of Environmental Pollution

Pesticides, PCBs, PAHs, and metals are the most common chemicals monitored in the coastal systems (O'Connor 2002). These chemicals are generally present in heavily used coastal zones and, accordingly, have been the focus of monitoring programs to determine status and trend of chemical pollution. One of the most comprehensive exposure monitoring programs in the United States, the National Marine Fisheries Service Status and Trends Program Mussel Watch Project, uses soft tissue concentrations in sentinel mussels and oysters to characterize local exposure conditions in relation to other locations (O'Connor & Ehler 1991, O'Connor 2002). Bivalves, presumably because of their filter-feeding behavior, are notorious for their ability to concentrate metals. This characteristic has provided an opportunity to use bivalves to monitor environmental chemicals that are otherwise below detection in the water column or that are highly variable over time.

Bivalve tissue concentrations used in the Mussel Watch Project and other environmental monitoring programs are better used to characterize long-term trends than to estimate actual exposure concentrations (Kopfler & Mayer 1973, Ikuta 1958a, Ikuta 1958b, Roesijadi 1996, O'Connor 2002). Individual bivalves, even when exposed to the same ambient concentrations of chemicals, can accumulate different tissue concentrations. This is shown by the substantial variability among oysters sampled at the same time and location. Some concentrate elements with such effectiveness that they have been termed "super-accumulators" (Lobel & Wright 1983, Wright et al. 1985). Variability in accumulation is often linked to size, age, filtration rate, and reproductive status, but can also vary with environmental factors that include salinity, food availability, and chemical speciation (Chipman et al. 1958, Boyden & Phillips 1981, Phelps & Hetzel 1987, Wright & Zamuda 1987, Bryan & Langston 1992, Roesijadi 1996). Such differences have led to the general conclusion that 15 to 25 oysters (Fig. 5) must be analyzed to provide a representative estimate of metal concentrations for a given site (Kopfler & Mayer 1969, Gordon et al. 1980, Boyden & Phillips 1981, Wright et al. 1985, Sanders et al. 1991, Reidel et al. 1995, Jiann & Presley 1997).

Variable accumulation has confounded interpretations of bivalve tissue analysis and has limited its effectiveness as an indicator of environmental exposure. As Roesijadi (1996) states,

"A consensus on the best approaches for using the metal content of oysters to monitor environmental metal contamination has yet to emerge, although the use of oysters as sentinel organisms is a common activity." (Roesijadi 1996, p. 520)

To offset this variability, monitoring programs often monitor during the same season each year and use animals of similar size. Other approaches include the use of inbred organisms in transplant scenarios (Roesijadi 1996).

High Concentrations of Copper and Zinc are Accumulated in Oysters

Despite uncertainties in interpreting tissue concentrations, evidence supporting zinc as the most prominent element in eastern

Figure 5. Percentage deviation of the cumulative mean for zinc (X) and copper (O) concentrations from the population mean (defined as 34 animals collected from 9 different sites) determined by Wright et al. (1985) using eastern oysters from Chesapeake Bay. Data from all collections were randomized and then computed as a cumulative mean, starting with two animals and progressing to 34 animals. Data were pooled by ignoring whether deviations were positive or negative.

oyster tissues is overwhelming (Table 3). Zinc is usually followed in quantity by copper (Shuster & Pringle 1969, NOAA 1987) or iron (Lytle & Lytle 1990, Jiann & Presley 1997). Concentrations of zinc invariably comprise 80% or more of the total metal accumulated in eastern oysters, a proportion unique among marine invertebrates (Vinogradov 1953, Pequegnat et al. 1969) and even among filter-feeding bivalves (Pringle et al. 1968, Boyden & Romeril 1974, Boyden 1975). O'Connor (2002) reported that eastern oysters accumulated about 10 times the copper, silver, and zinc of mussels *Mytilus edulis*. This finding is upheld by relatively long-term data collected through the Mussel Watch Project (O'Connor 1996, Table 4), as well as direct comparisons of mussel and oyster collections from the same sites in Long Island Sound (O'Connor 1994) and Chesapeake Bay (Reidel et al. 1995).

Copper has also been found particularly high in oysters relative to other lamellibranchs (Vinogradov 1953, Brooks & Rumsby 1965).

"Except for species of Ostrea, all Lamellibranchiata contain copper in quantities not higher than the average amount found in Gastropoda . . . species of Ostrea have proved to be richest in copper." (Vinogradov 1953, pp. 349–350)

Copper, as described earlier, can be extremely high in oysters exhibiting a green tint. Hiltner and Wichmann (1919) found a mean of 403 μg copper g^{-1} (dry weight) for normal "white" oysters in the northeast United States (see Table 3), but noted that bluish oysters collected from Perth Amboy, NJ, contained 7,435 μg g^{-1} . Similarly, Galtsoff and Whipple (1930) found green oysters to contain 1,954 μg copper g^{-1} , much higher than the mean 109 μg g^{-1} they recorded for white oysters.

Crassostrea virginica may accumulate more copper and zinc than *C. gigas*. Pringle et al. (1968) found from broad geographic surveys that eastern oysters along the Atlantic coast contained 5 to 10 times the zinc and copper as Pacific Coast *C. gigas*. Okazaki and Panietz (1981) found higher accumulations of zinc (but not copper) in *C. virginica* than *C. gigas* at a site in California. Boyden (1975) found *O. edulis* to accumulate more zinc and less copper than *C. gigas* sampled from the same site. Although there is some

consistency among reports, inferences from these data must be tempered by recognition of the high variability noted above.

Copper and Zinc Are Accumulated in Granular Amebocytes

Orton (1923) was among the first to measure high concentrations of copper and zinc in oyster amebocytes. During the summer of 1920, *O. edulis* in the commercial oyster beds of the Thames Estuary suffered unusually high mortalities. Because mortality

TABLE 4.

Annual (1986–1993) geometric mean concentrations ($\mu\text{g g}^{-1}$ dry wt) of selected metals in soft tissues of oysters *C. virginica* (composite of 20 for each site) or mussels *Mytilus edulis* (composite of 30 for each site) collected from 154 sites across the US, as reported from the NOAA National Status and Trends Mussel Watch Project (O'Connor 1996). Oysters generally accumulate $>10\times$ the copper and zinc (and silver, O'Connor 2002) accumulated by mussels.

events were frequent during 1919 to 1921 in Europe (Italy, France, the Netherlands, Ireland, and in several regions of England), Orton postulated a relationship to wartime contamination, (i.e., hazardous munitions and material strategically dumped or lost from damaged and sunken ships). Accordingly, he examined *O. edulis* for concentrations of trinitrotoluene, nitrites, oil, and metals. Metals in Thames Estuary oysters were low, so metal toxicity was excluded. Yet, his investigations revealed that the amoebocytes of oysters could contain high concentrations of copper ($25,900 \mu\text{g g}^{-1}$ dry weight, using $5\times$ wet weight values), zinc ($40,650 \mu\text{g g}^{-1}$) and tin ($2,450 \mu\text{g g}^{-1}$). These concentrations were many times higher than whole animals or sediments from the same location. Orton (1923) inferred from his findings that most, if not all metals in oysters were concentrated in amoebocytes.

His investigation led to another intriguing conclusion. When he transplanted metal-laden oysters to environments with low metal concentrations, they eventually eliminated their metal burdens. Rather than steady-state equilibria, he suggested a novel route of elimination.

"It seems possible that metals are excreted by the blood-cells leaving the body of the oyster and carrying the metals with them." (Orton, 1923, p. 17)

Orton's (1923) contributions to the field were thus 3-fold. His studies sustained earlier speculation that green oyster amoebocytes had high concentrations of copper; he suggested that zinc, tin, and possibly other metals were retained in amoebocytes; and he proposed a novel method for elimination of metals (i.e., exomigration of amoebocytes).

The chemical nature of the green pigment in amoebocytes was systematically investigated in 1927 when Paul S. Galtsoff and Samuel Lepkowsky applied "microchemical reactions" to paraffin-embedded sections of normal and green-colored American oysters from New England (Galtsoff & Whipple 1930). Treatment with potassium ferrocyanide and hematoxylin confirmed fully the speculations of Herdman and Boyce (1899) that the intensity in green color was in proportion to the copper content in the oyster and that the copper was located almost exclusively in the green leukocytes (amoebocytes).

Ultimately, a detailed characterization of both copper and zinc in oyster amoebocytes was provided by Craig L. Ruddell (1971) in research published from his doctoral dissertation. He used traditional and novel histochemical staining techniques to locate both

of the metals in membrane-bound granules (lysosomal derivatives) in amoebocytes of Pacific oysters, *C. gigas*. Amoebocytes laden with copper and zinc were found distributed throughout the hemolymph and tissues. Neither metal was found in any other cell types, including gill and mantle epithelial cells. It seems that some amoebocytes (basophilic granular amoebocytes, BGA) contained primarily zinc, whereas others (acidophilic granular amoebocytes, AGA) contained primarily copper (as presaged by Boyce & Herdman 1897, p. 33). Even so, Ruddell suggested that some amoebocytes might store both elements. He did not report on other metals, (e.g., tin [Orton 1923], iron [Galtsoff 1938, Galtsoff 1953] and manganese [Galtsoff 1964]), that might also be retained and transported by amoebocytes.

Positive Association of Metal Content with Amoebocyte Number and Distribution

Ruddell later hypothesized that concentrations of copper and zinc in different oyster tissues would reflect the tissue distribution of amoebocytes. He examined *C. gigas* and *C. virginica* from both contaminated and reference sites and established that a positive correlation existed between the number of tissue amoebocytes and tissue concentrations of copper and zinc (Ruddell & Rains 1975). Mantle tissues of oysters from element-rich sites had higher zinc and copper in their amoebocytes than those from element-poor sites. In addition, zinc concentrations in the mantle were found linearly and positively associated with the number of BGAs counted in mantle histologic sections (Table 5). This relationship was reinforced by a positive association between BGAs and zinc concentrations derived from examination of mantle (high zinc) and digestive diverticulum (low zinc) tissues from the same oysters. Copper analyses yielded similar trends, but the linear association between amoebocytes and copper concentrations was not as distinct as that of zinc. The fact that copper was associated primarily with AGAs rather than BGAs (Ruddell 1971) might have created this difference.

Overall, the results of Ruddell & Rains (1975) established a positive relationship for copper and zinc with amoebocyte number and distribution. The metals occurred wherever metal-carrying amoebocytes were stationed, sometimes in the adductor muscle and pericardial sac but more often in the gills, mantle, labial palps, gonad, and digestive gland. Ultimately, Ruddell and Rains (1975) used data from both *C. gigas* and *C. virginica* to estimate that

TABLE 5.

Tissue concentrations (dry weight) of zinc and copper were associated with the density (number per unit area) of basophilic amoebocytes observed in histological sections of Pacific (*C. gigas*) and eastern (*C. virginica*) oysters by Ruddell Rains (1975), which provides statistical information. Metal analyses were performed on whole oysters, mantle, and digestive diverticulum (dig. div.) tissue.

Sample	Species	Density of Basophils	Tissue Analyzed	[Zn] $\mu\text{g g}^{-1}$	[Cu] $\mu\text{g g}^{-1}$
1	<i>C. gigas</i>	44.5	Whole	336	149
			Mantle	328	129
			Dig. div.	214	61
2	<i>C. gigas</i>	85.4	Whole	422	19
			Mantle	1,039	47
			Dig. div.	400	18
3	<i>C. gigas</i>	189.2	Whole	429	482
			Mantle	1,508	900
4	<i>C. gigas</i>	346.4	Whole	1,656	319
5	<i>C. virginica</i>	213.7	Whole	1,335	290

			Mantle	5,285	968

nearly all of the zinc (and probably copper) in an oyster was retained within amoebocytes.

Localization of Copper and Zinc in Amoebocyte Granules

Robert S. Brown (1975), in his doctoral dissertation, further characterized the relationship of copper and zinc with circulating amoebocytes of eastern oysters. Using *C. virginica* from Maryland, Brown applied histochemical techniques to show that copper and zinc were localized in membrane-bound intracellular granules. Virtually all intracellular granules stained positive with Mallory's hematoxylin for copper (Fig. 6) or with a fluorescent dye labeled specifically to bind with zinc (Fig. 7). Nongranular portions of cytoplasm and agranular amoebocytes were not stained by either chemical. Transmission electron microscopy (unstained sections)

Figure 6. Mallory's hematoxylin stain for copper demonstrates a dark blue color in granular amoebocytes of *C. virginica* ($\sim 900\times$). Color occurred in most of the cytoplasmic granules but not in the agranular cytoplasm. Agranular cells (arrows) did not stain positively for copper. (Reproduced from Brown 1975; Fig. 18, with permission of the author).

Figure 7. Zinc demonstrated in *C. virginica* amoebocytes using fluorescence of 8-hydroxyquinoline complexes ($\sim 600\times$). An intense greenish-yellow fluorescent color developed within pleomorphic amoebocyte granules. (Reproduced from Brown 1975; Fig. 20, with permission of the author).

showed that only the intracellular granules of amoebocytes exhibited the electron-dense signature of metals (Fig. 8). High-density material was confined inside the granules, and was not bound by a separate membrane distinct from that of the granule (Fig. 9). Brown concluded that the cytoplasmic granules of amoebocytes, the same granules described for *C. gigas* by Ruddell (1971), were storage sites for electron-dense metals.

Brown (1975) was also able to quantify copper and zinc within amoebocytes using a relatively novel technique that coupled energy dispersive x-ray analysis to scanning electron microscopy (EDAX-SEM; Fig. 10). Nearly all of the 250 amoebocytes probed with EDAX-SEM contained both copper and zinc, although a few cells contained only zinc. The metals were absent from nuclei and from agranular portions of the cytoplasm. Brown determined that *C. virginica* amoebocytes could contain as much as 0.3% of their dry weight in copper and 9% of their dry weight in zinc (Table 6). Using EDAX-SEM data, he calculated the content of a single amoebocyte to be 6.0×10^{-13} g Cu and 2.5×10^{-11} g Zn, and the content of a single amoebocyte granule was 8.5×10^{-15} g Cu and 3.5×10^{-13} g Zn. These calculations assumed 89% granular amoebocytes in a sample and 71 granules per cell. Using the same technique, cell-free hemolymph was found to contain copper at an average $0.159 \mu\text{g mL}^{-1}$ and zinc at an average $8.372 \mu\text{g mL}^{-1}$.

These reports of metal accumulation in amoebocytes of *C. virginica* led George et al. (1978) to examine "green-sick" *O. edulis* collected from metal-polluted sites in Cornwall, England, as a representative model for studies of bivalve metal detoxification. Their approach included a technique similar to that used by Brown (1975). Using X-ray microprobe analysis (XRP-TEM, a dispersed energy detector coupled to transmission electron microscopy), they located and quantified electron-dense elements within cells. Comparisons of numerous tissues confirmed for *O. edulis* the earlier

Figure 8. Transmission electron micrographs of unstained granular amoebocytes demonstrate the electron opacity (density) of granules in comparison to the nucleus (N) and cytoplasm (C). The top whole-mount was fixed in glutaraldehyde and the bottom was air-dried ($\sim 4000\times$). (Reproduced from Brown 1975; Fig. 21 with permission of the author).

findings on *C. gigas* and *C. virginica*; copper and zinc were localized exclusively within amoebocytes. Further confirming the work of Ruddell (1971), George and co-workers found two types of metal-containing amoebocytes, BGAs that contained zinc in 1- μm -diameter granules and AGAs that contained copper in 0.8- μm -diameter granules. Analysis of hemolymph and cell-free plasma showed that 70% to 77% of the copper and zinc in the hemolymph was contained in the circulating amoebocytes. This estimate, and others comparing hemolymph to cell-free plasma, may well have been influenced by loss of metals from the amoebocytes during centrifugation and processing.

Members of the same research team (Pirie et al. 1984) later showed that amoebocytes from *O. edulis*, *C. gigas*, and *O. angasi* all had a capacity to accumulate copper and zinc. The latter two species were reported to possess a single cell type that accumu-

Figure 9. Higher-power transmission electron micrographs provided evidence that the electron dense material of amoebocytes resided completely within the membranes of the cytoplasmic granules, shown here ($\sim 86,000\times$). There was no evidence of a separate membrane around the electron dense material. (Reproduced from Brown 1975; Fig. 22, with permission of the author).

lated both copper and zinc, whereas *O. edulis* had copper-specific cells and zinc-specific cells as well as nonspecific copper/zinc (mixed) cells. The metal-specific cells in *O. edulis* were found only from a high-metal environment and mixed cells were from less contaminated sites. The authors acknowledged a possibility that the amount or type of metal present in the environment might have influenced the proportion of different cell types in their studies.

Thomson et al. (1985) compared metals in different cells of *C. gigas* from Tasmania and Wales. Whole body metal analyses showed that oysters from Tasmania contained approximately twice the copper and zinc concentrations of the Welsh specimens, yet XRP-TEM analytical results showed that individual amoebocytes from the two groups of animals contained about the same concentrations (see Table 6). This supported the proposition of Ruddell and Rains (1975) that the copper and zinc concentrations were linked to amoebocyte number. Thomson et al. (1985) estimated that amoebocytes contained $\sim 90\%$ of the copper and zinc in gill and mantle tissues and calculated the concentrations in amoebocyte granules to be 506 μg copper g^{-1} and 6,375 μg zinc g^{-1} (dry weight, converted from mM kg^{-1}), values much less than estimates for *O. edulis* (Orton 1923) and *C. virginica* (Brown 1975).

Figure 10. Analysis of an eastern oyster amebocyte granule using EDAX-SEM microanalysis. Top: scanning electron micrograph of a granular amebocyte ($\times 3,300$) showing the specific granule analyzed (arrow). Bottom: Result of EDAX analysis of an amebocyte granule. X-ray energy (keV) is represented on the x-axis and x-ray emission intensity on the y-axis. Emission detection was greatest at 8.0 and 8.6 keV, corresponding to copper and zinc, respectively. (Reproduced from Brown 1975; Figs. 25 and 26, with permission of the author).

ACTIVE, CONTROLLED UPTAKE AND RETENTION OF COPPER AND ZINC

Copper and zinc accumulation in eastern oysters is so great that many have dismissed the possibility of a physiologic role (Hiltner & Wichmann 1919, Pequegnat et al. 1969, Wolfe 1970a). For copper, at least, high accumulation has even been related to toxicity or disease (Ryder 1882, Herdman 1896, Boyce & Herdman 1897, Korringa 1952). This has led to an overriding impression that copper and zinc are in excess and sequestered in oyster amebocytes solely to prevent toxicity.

"Iron, copper, and zinc maybe be stored in the tissues and in some blood cells as excess materials which are slowly eliminated." (Galtsoff 1964, p. 390)

Simkiss & Mason (1983) introduced three theories to explain the magnitude of copper and zinc deposits in oyster amebocytes: (1) Metals are phagocytosed as foreign material by amebocytes but, being resistant to digestion, are accumulated in the cytoplasm; (2) amebocytes are a specific detoxification system that remove metal ions from the hemolymph to keep concentrations below toxic levels; (3) amebocytes accept metals from other cells (e.g.,

gill cells) to transport them through the blood stream to other tissues (e.g., kidney) for storage and eventual excretion. Yet, to the authors, none of these theories were totally satisfying:

"Many of the more easily detected accumulations of metals in molluscs are tissue specific and they are often associated with particular deposits of granules. These are almost universally interpreted as detoxification or excretory systems, but there is as yet virtually no acceptable experimental evidence for such a conclusion." (Simkiss & Mason 1983, pp. 154-155)

In fact, for eastern oysters, any perception that copper and zinc are sequestered simply for eventual elimination is confounded by an assortment of existing data. Eastern oysters do not seem harmed by high concentrations of copper or zinc in the ambient environment or by high concentrations accumulated in their tissues. Rather, they seem to accumulate copper and zinc only when they have the amebocyte capacity to safely do so. When amebocytes are available, oysters can accumulate copper and zinc from low ambient concentrations and retain them even though effective elimination mechanisms are available. These considerations, described below, not only refute a perception that copper and zinc are sequestered solely for detoxification and elimination, but sustain a contingency that they are stored for a physiologic purpose.

OYSTERS CONCENTRATE COPPER AND ZINC FROM LOW AMBIENT WATER CONCENTRATIONS

Comparisons of oyster soft tissue concentrations with ambient water concentrations of copper and zinc have clearly demonstrated preferential accumulation (Korringa 1952, Boyden & Romeril 1974, Boyden 1975, Simkiss et al. 1982, Roesijadi 1996). Hunter & Harrison (1928) found high concentrations of copper and zinc in eastern oysters had no direct relationship to body weight, other metals, or concentrations in the seawater. They concluded,

"There is reason to believe that oysters will absorb from the water almost any substance which it contains." (Hunter & Harrison 1928, p. 9)

Moreover, it was apparent from even the earliest reports (e.g., Boyce & Herdman 1897) that these metals could be accumulated from metal-poor environments. Measured tissue concentrations have been so high that active, selective uptake seemed inevitable.

"The high proportions of zinc and copper in oysters from beds in the vicinity of industrial plants using these metals can be readily accounted for. The high zinc content of those from beds far removed from any known source of metallic contamination may be explained by the probability that oysters gradually remove traces of the metals from the water and store them in their tissues." (Hunter & Harrison 1928, p. 8).

There is evidence that zinc is more avidly concentrated at low ambient water concentrations than at high. Chipman et al. (1958) compared zinc concentrations of eastern oysters and seawater from several locations along the US Atlantic seaboard. Zinc content was higher in oysters from locations with high ambient zinc, but concentration factors were five times higher at the lowest ambient concentration (Table 7). Preston (1966) estimated a 10^5 concentration factor for zinc. Copper is also concentrated from ambient waters (Ikuta 1958a, 1958b, Pringle et al. 1968, Shuster & Pringle 1969, Kopfler & Mayer 1973). Roesijadi (1996) concluded that uptake of anthropogenic copper and zinc is superimposed on an

TABLE 6.

Concentrations ($\mu\text{g g}^{-1}$ dry weight) of copper and zinc in amoebocytes reported for various oyster species. Ruddell and Rains (1975) estimated zinc comprised 6% of the amoebocyte cell weight in *C. virginica*. Brown (1975) estimated zinc to be 9% and copper 0.3% of the cell weight. For *O. edulis*, Orton (1923) estimated that zinc comprised 4.1% and copper 2.6% of the amoebocyte cell weight. Thompson et al. (1985) estimated that mantle amoebocytes retained 93% of the copper and 85% of the zinc in the mantle, and that gill amoebocytes retained 90% of the copper and 90% of the zinc in gill tissues.

Species	Source	Method	Cell Type	Amebocyte [Cu]	Amebocyte [Zn]

already strong natural proclivity. This capacity demonstrates the frailty of tissue analyses to detect pollution, and refutes any perception that metal uptake is passive and indiscriminate.

It is re-emphasized that the substantial concentrations of zinc and copper in eastern oysters are almost exclusively confined to the granules of amoebocytes (Section II). Zinc and copper distribution in oysters is thus determined by the number and distribution of amoebocytes in different tissues (Ruddell & Rains 1975) and their individual capacity to retain the elements in granules. Concentrations of copper and zinc are high in oysters, higher in granular amoebocytes, and even higher in amoebocyte granules, underscoring the conclusion of George et al. (1978) that copper and zinc are actively recruited into granules against a strong chemical gradient. Even so, there has been no published investigation of the mechanism of uptake and no evidence of metabolic cost. Galtsoff and Whipple (1930) compared oxygen consumption rates of 'normal' eastern oysters from Onset Bay (MA) with green eastern oysters from New Haven Harbor (CT). Results showed a slight increase in oxygen consumption by green oysters, but the significance was

considered doubtful, based partly on the high variability attributed to muscular activity, gill ciliary activity, and season. Regardless, there seems little doubt that oysters must expend energy to assimilate and retain these metals, especially when they are scarce in the ambient environment.

Logarithmic Uptake of Copper and Zinc in Eastern Oysters

Metal content in tissues of bivalves and other organisms at any given time is the difference between two dynamic processes, influx (uptake rate) and efflux (release rate) (Roesijadi 1996). Changes in influx and efflux rates can be estimated by transferring organisms from low to high (to estimate influx) or high to low (to estimate efflux) exposure concentrations. The number of studies that examine influx outweigh those that examine efflux, but both are equally important in the ultimate disposition of metals in oysters.

Giann and Presley (1997) suggested that, in general, metals accumulate in oysters because of rapid uptake and slow elimination. Whereas rapid uptake may be accurate for most metals, copper and zinc exhibit a unique pattern. Shuster and Pringle (1969) continuously exposed eastern oysters in the laboratory to two elevated concentrations each of Cd, Cr, Cu, or Zn and followed their accumulation in soft tissues over a 20-week period. Upon exposure, cadmium and chromium showed an immediate spike in tissue concentrations that eventually slowed, presumably because they approached a steady state between influx and efflux (Fig. 11). The rate of uptake for copper and zinc, however, did not spike appreciably upon exposure. Instead, a consistent, logarithmic increase in tissue residues was maintained, without decline, throughout the study. Shuster and Pringle (1969) assigned these unexpected results to high initial tissue concentrations. More likely, the two accumulation patterns distinguished two different mechanisms of uptake. Cadmium and chromium exhibited a phased pattern typical of direct tissue absorption whereas the pattern for copper and zinc imply a controlled assimilation that might explain why oysters held in high ambient concentrations do not necessarily have high body burdens (Reidel et al. 1995).

Controlled uptake may be a consequence of the need to seques-

TABLE 7.

Zinc concentration factors of *C. virginica* at various sites in the US calculated from data of Chipman et al. (1958). Lower concentrations of zinc in the seawater coincided with lower zinc concentrations in the tissues, but higher concentration factors. Although not calculated by Chipman et al. (1958), this association was observed by both Preston (1966) and Wolfe (1970a). (Note: oyster tissue data is normalized to wet weight).

Location	Seawater (ng g^{-1})	Oysters ($\mu\text{g g}^{-1}$ wet)	Concentration Factor
Chesapeake Bay	24.0	2933	$\times 122,208$
Milford, CT	18.8	3174	$\times 168,830$
James River, VA	7.9	1484	$\times 187,848$
Beaufort, NC	4.6	1171	$\times 254,565$
Brunswick, GA	1.1	313	$\times 284,545$
Pensacola, FL	0.8	600	$\times 750,000$

Figure 11. Results of two experiments showing the accumulation of chromium, cadmium, copper, and zinc in eastern oysters maintained in a continuous exposure system for 20 wk. Two concentrations of each element were constantly added to natural seawater from Narragansett Bay, Rhode Island. Experiment A-67, represented on the left, was described in Pringle et al. (1968). Experiment A-68, on the right, was described in Shuster and Pringle (1969). Cadmium exposures were curtailed before wk 20 (X) due to high mortalities. (Figures redrawn from Shuster and Pringle 1969; Figs. 2 and 3).

ter copper and zinc in amoebocyte granules. Only a limited number of granules exist in an amoebocyte (~71 granules, as estimated by Feng et al. 1971), so there is a limited amount of each element that can be retained (amoebocyte metal-carrying capacity). Additional uptake of copper and zinc from ambient sources would be limited until new cells become available. The logarithmic rate of accumulation observed by Shuster & Pringle (1969) seems consistent with this supposition; although cell proliferation has not been well characterized, new cells are probably produced at a logarithmic rate. The fact that uptake might be controlled by a physiologic condition (i.e., the availability of amoebocytes with metal-carrying capacity), challenges any perception that copper and zinc are indiscriminately absorbed from metal-rich environments. Rather, it seems that they are actively incorporated when (and only when) amoebocytes with metal-carrying capacity are available. Once this capacity is exceeded, further accumulation requires recruitment of new amoebocytes, either through proliferation (i.e., hemopoiesis) or activation of existing amoebocytes.

Slow Elimination of Copper and Zinc by Eastern Oysters

Just as transfer of oysters from a reference to contaminated site can be used to estimate influx, the converse can provide insight to efflux, or elimination of chemicals. By transferring eastern and Pacific oysters in California from a contaminated to a reference site, Okazaki and Panietz (1981) estimated efflux of various metals. They monitored the loss of metals over a 56-d period from the mantle, gill, digestive gland and kidney, and calculated biologic half-lives ($B_{1/2}$) for each tissue. Half-lives for all four metals tested (Ag, Cu, Hg, Zn) were particularly long for eastern oysters (Table 8), and generally 5x longer than those for *C. gigas*. Ruddell and Rains (1975) had earlier found higher concentrations of copper and zinc and higher numbers of basophils in *C. virginica* than in *C. gigas* from these same two sites. It seems that eastern oysters retain

TABLE 8.

Biological half lives of selected metals as calculated by Okazaki and Panietz (1981) from concentrations in specific tissues of *C. virginica* and *C. gigas* removed from a contaminated site (Redwood Creek) and deployed for 56 d at a reference site (Tomales Bay) in California.

	Tissue Concentrations ($\mu\text{g g}^{-1}$ dry)		Biological Half-Life (d)
	Contaminated	Reference	
<i>C. virginica</i>			
Ag	143	9.5	149.1
Cu	1,548	438	156.2
Hg	3.36	0.38	133.5
Zn	14,365	5,490	183.9
<i>C. gigas</i>			
Ag	162	3.2	26.4
Cu	1,504	93	32.9
Hg	4.26	0.24	23.3
Zn	5,531	474	36.7

^a Average of concentrations determined from mantle, gill, digestive gland and kidney on day 0 from both sites (25 oysters).

^b Average determined from estimates of half-life in separate tissues (mantle, gill, digestive gland and kidney) of oysters transplanted from the contaminated to the reference site for 56 d (5 groups of 5 oysters).

metals for a relatively long period, and significantly longer than Pacific oysters.

Other studies have reached similar conclusions. Zaroogian (1979) collected oysters from Long Island Sound (New York) and held them in seawater troughs for 56 weeks to examine depuration of copper and cadmium. Copper concentrations in the troughs ranged from 1–2 $\mu\text{g L}^{-1}$. He found no statistically significant decrease in copper during this time, and actually noted an increasing trend. Greig and Wenzloff (1978) transferred eastern oysters from a contaminated site (Housatonic River, CT, USA) to an uncontaminated site (Beaufort, NC, USA) and found silver, cadmium, and zinc did not substantially decrease during 40 weeks, and copper was marginally decreased on only one (27-wk) sampling date.

Slow efflux of copper and zinc from eastern oysters indicates that, because even though amoebocytes are proficient at detoxifying copper and zinc (i.e., sequestering large amounts in membrane-bound granules), they are strikingly inefficient at eliminating them. This inability is not for lack of a physiologic mechanism. The most likely means for oysters to eliminate copper and zinc is amoebocyte exomigration.

"Amoebocytes seem to have an important phagocytic role during excretion in molluscs, particularly in eliminating insoluble particles from the circulation. The wandering amoebocytes phagocytose the particles and migrate to the gut, the pericardium, the excretory organs or the mantle cavity; they either move out of the body through these viscera or return after releasing the particles." (Naraïn 1973, p. 8)

This is, of course, the same elimination mechanism anticipated by Orton (1923), Yonge (1928) and others who observed exomigration of green, copper-bearing amoebocytes in oyster pseudofeces. Since then, amoebocyte exomigration has been described as a means for oysters to eliminate a variety of ingested materials, including india ink, carmine dye, neutral red, aniline oils, coal tar,

iron, and fluorescent beads (Takatsuki 1934, Ranson 1936, Stauber 1950, Galtsoff 1953, Ruddell 1971). In one report, Galtsoff (1953) suggested that iron was actively ingested and then eliminated by amoebocytes passing across the mucous cells of the gill and mantle. Potts (1967) considered the evidence for amoebocytic elimination strong enough to permit an analogy of these cells with the reticulo-endothelial system of vertebrates.

A description of amoebocyte exomigration in *C. virginica* was provided by Stauber (1950), who injected india ink into oyster hearts and collected samples over a 42-day period for gross and microscopic examination.

"The ink suspensions agglomerated readily and produced emboli which virtually occluded the arterial vessels of viscera, mantle and adductor muscle. Subsequent events, with considerable overlapping, were in sequence: (a) phagocytosis of the injected ink particles by mobile phagocytes, (b) distribution of the ink in the phagocytic amoebocytes to all parts of the organism with concomitant resolution of the emboli and (c) eventual elimination of the ink from the organism by the migration of ink-laden phagocytes through the epithelial layers of the alimentary tract, digestive diverticula, palps, mantle, heart and pericardium into lumina from which they were voided." (Stauber 1950, pp. 239–240)

The presence of ink-darkened *'dejecta and rejecta'* supported Stauber's conclusion that the bulk of the injected ink was eliminated by migration of amoebocytes into lumina that opened to the outside of the oyster. A similar process had been described for *O. edulis* by Takatsuki (1934), who showed that carmine particles injected into the body of the oyster were ingested by amoebocytes and then distributed into excretory tubules, pericardial epithelium, gonoducts, rectum, mantle cavity and blood vessels. The presence of carmine-containing amoebocytes in the mantle cavity provided evidence that they traversed epithelial layers to be discharged in the pseudofeces.

A mechanism is thus available to eastern oysters to eliminate metals and other substances but, by all indications, is not used for copper and zinc. Both metals are retained in the oyster amoebocytes at high concentrations for periods well beyond that needed for exomigration. In all likelihood, retention of copper and zinc exceeds many times over the life span of an individual amoebocyte, implying that the elements are re-incorporated into new cells. This is probably achieved through phagocytosis of damaged and dead amoebocytes (Scro & Ford 1990), and may include apoptosis, wherein damaged and senescent amoebocytes pinch off cytoplasmic fragments that are ingested by younger amoebocytes without an inflammatory response (Sanderson 1982, Sunila & LaBanca 2003). Metals sequestered in amoebocyte granules could be retained through numerous amoebocyte cell cycles.

No Evidence of Lethal Copper or Zinc Toxicity to Eastern Oyster Adults

The sensitivity of embryonic and larval stages of *C. virginica* to water-borne metal toxicity has been well documented. Results of 2-day embryo tests (Calabrese et al. 1973) showed copper to be 100% lethal to eastern oyster embryos at 130 $\mu\text{g L}^{-1}$ water concentrations ($\text{LC}_{50} = 103 \mu\text{g L}^{-1}$) and zinc to be 100% lethal at 500 $\mu\text{g L}^{-1}$ ($\text{LC}_{50} = 310 \mu\text{g L}^{-1}$). In a subsequent study, MacInnes (1980–81) demonstrated a synergistic toxicity for copper and zinc in eastern oyster embryos at concentrations of 8–16 $\mu\text{g Cu L}^{-1}$ and 100–200 $\mu\text{g Zn L}^{-1}$. For larvae of *C. virginica*, Calabrese et al. (1977) estimated lethal copper toxicity for a 12-day exposure

as $\text{LC}_{50} = 32.8 \mu\text{g L}^{-1}$, with growth of surviving larvae reduced by 30%. Prytherch (1934) noted that larval exposure to very high copper (>800 $\mu\text{g L}^{-1}$) would prove lethal even with very short exposure periods (minutes to hours).

In contrast, there is little evidence of water-borne toxicity to adult oysters. One early study attempted to characterize anticipated toxic effects:

"In the first place, we tried the effect of pieces of copper, copper filings, and copper dust lying in the bottom of the aquarium; and similarly, of steel filings, old rusty nails, and other fragments of iron. We also kept oysters for some time in an old copper vessel, and along with copper pyrites and other ores of copper. None of these gave any definite result." (Herdman & Boyce 1899, p. 32)

In subsequent experiments however, they exposed eastern oysters to 50 grains of copper oxide in a gallon of water, which nominally resulted in some green coloration and some mortality within a few weeks. Other than this unsubstantial report, there have been no definitive demonstrations of lethality for copper or zinc exposures to adult eastern oysters. This is underscored by O'Connor (2002), who reviewed a large data set compiled by Jarinen and Ankley (1999) on chemical effects to survival, growth, and reproduction of aquatic organisms: there were no data relating lethal effects of copper or zinc to adult eastern oysters. This intriguing lack of evidence led Roesijadi (1996) to conclude that adult eastern oysters are tolerant of high copper and zinc concentrations in the water column and in their tissues.

There is some published evidence of "negative" toxicity test results. In two carefully controlled, continuous-exposure experiments (Shuster & Pringle 1969), there were no lethal consequences to eastern oysters exposed to copper and zinc, even though tissue concentrations were significantly elevated over the 20-week exposure (see Fig. 11). Cadmium (100 and 200 $\mu\text{g L}^{-1}$) caused significant mortalities, but not copper (25 and 50 $\mu\text{g L}^{-1}$), zinc (100 and 200 $\mu\text{g L}^{-1}$), or chromium (50 and 100 $\mu\text{g L}^{-1}$). Copper accumulated in the oyster tissues to over 5000 $\mu\text{g g}^{-1}$ (dry wt) and zinc to over 15,000 $\mu\text{g g}^{-1}$. There are, furthermore, numerous examples of extremely high concentrations of copper and zinc accumulated in apparently healthy eastern oysters (see Table 3). Frazier (1975, 1976) found adult *C. virginica* survived elevated concentrations of copper in experimental studies, but the shells deposited during this time were thinner and weaker. Okazaki (1976) showed copper toxicity to adult *C. gigas*, but at very high concentrations (96-h median tolerance limit = 560 $\mu\text{g L}^{-1}$) so this species may also be relatively tolerant.

It is not clear how sequestration in granules prevents copper and zinc toxicity. The membranous lining of the granules may shield vulnerable tissues, or the metals may be complexed within the granules so they are unavailable to vulnerable tissues. As long as additional uptake requires generation of new amoebocytes and their protective granules, elevated ambient water concentrations will not lead to oyster toxicity. However, this mechanism relies on the ability of amoebocytes to capture incoming (ambient) copper and zinc before contact with vulnerable tissues. Most likely, this phase is achieved through binding of the metals to mucus in the mantle cavity, as proposed below.

Mucus Capture of Ambient Copper and Zinc

Any water-borne or food-borne element entering an oyster first encounters the copious mucus covering all external surfaces of the soft tissues (Fig. 12). Hillman (1968, 1969) investigated cellular

ALTERNATIVE FATES OF CHEMICALS IN BIVALVES

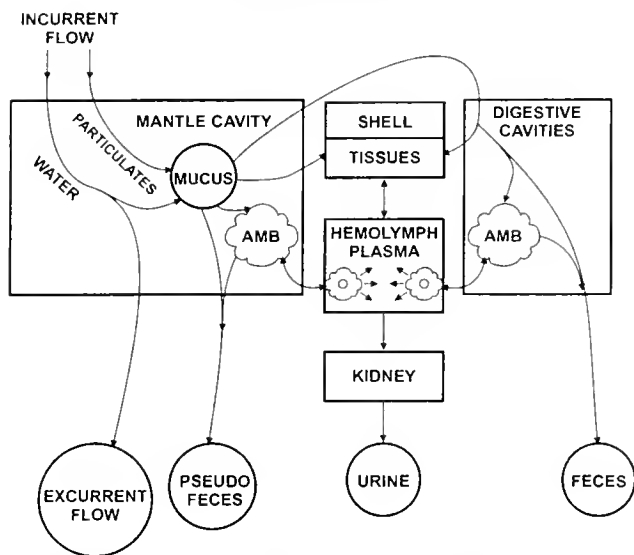

Figure 12. Schematic diagram of potential fates for incurrent soluble and insoluble materials in oysters. Ameobocytes (AMB) are capable of moving throughout the oyster with material or abandoning the oyster (exomigration) to carry away unwanted particles in the pseudofeces or feces. Ameobocytes in the digestive cavities are believed to play a primary role in nutrition through phagocytosis of incoming particles. (This diagram was based on a model for zinc dynamics published by George and Pirie 1980; Fig. 8).

and compositional differences of mucus in *Mercenaria mercenaria* and concluded that mucus was, "playing far more sophisticated roles in the life activity of the clam than previously suspected" (Hillman 1978, p. 21). These roles include organismal protection, lubrication, and food capture. Mucus of bivalves contains complex carbohydrate sulphates that operate as an ion-exchange mechanism to capture and retain particles and elements (Pringle et al. 1968), especially divalent cations such as copper and zinc (Korringa 1952). If toxic metals were bound to mucus, then they would no longer be available for direct absorption into vulnerable tissues. Instead, they would flow with the mucus sheets across tissue surfaces toward the mouth for elimination (pseudofeces) or ingestion (alimentary tract). This is a common path for selection of oyster food particles (Loosanoff 1949, Menzel 1955); eastern oysters are capable of preferentially ingesting organic particles while rejecting inorganic particles with the pseudofeces (Newell & Jordan 1983). If bound to mucus, water-borne copper and zinc entering the mantle cavity could be eliminated without ever contacting vulnerable tissues.

Accumulation, however, could still be achieved through ameobocyte phagocytosis of metal-laden mucus and metal-laden food particles trapped in the mucus. Through diapédesis, ameobocytes enter both the mantle cavity and the alimentary tract to capture mucus and food. The process of phagocytosis includes formation of phagosomes, cytoplasmic inclusions (Section V) that exhibit membrane structures similar to copper- and zinc-bearing granules. Metals might be retained in the phagosome after food particles and mucus are digested. If so, phagosomes may be the precursors to cytoplasmic granules. Other possibilities for uptake of metals exist. In particular, vertebrate phagocytes have displayed natural re-

sistance-associated macrophage protein (nramp) activity that transports metal ions for defensive purposes (Atkinson & Barton 1998, Jabado et al. 2000). It is believed that nramp proteins remove divalent cations from phagosomes, thereby depleting phagocytosed microorganisms of essential elements. Accumulation or retention of metals in oyster ameobocyte granules might use a similar, albeit inverted, process.

A Presumptive Biologic Function for Copper and Zinc

Information has been presented to dispel any perception that copper and zinc are sequestered by oysters solely to avoid toxicity. Ameobocytes acquire high concentrations of copper and zinc from low ambient concentrations and retain them for relatively long periods despite the potential for elimination by exomigration. Retention of copper and zinc may exceed the life span of an individual ameobocyte. The lack of toxicity to eastern oyster adults, even at high water and high tissue concentrations, is most likely attributable to binding of the metals by mucus and sequestration in membrane-lined granules of ameobocytes. These findings support speculation that eastern oysters store high amounts of copper and zinc for eventual use in critical physiologic functions. The following section provides evidence that antimicrobial activity is one of those functions.

HEIGHTENED AMEOCYTE ACTIVITIES AT CONTAMINATED SITES

Any attempt to understand the effects of chemicals on bivalve defense capacity must confront the conceptual obstacles noted at the beginning of Section II; the types and concentrations of chemicals vary in the water column over time and each chemical exhibits a unique rate of assimilation and elimination. Furthermore, variability in the natural environment can influence ameobocyte defense responses (Fisher 1988). Oysters are poikilothermic and osmoconforming, so the frequent fluctuations in temperature and salinity of estuarine and coastal waters are reflected in oyster tissues. Temperature and salinity are both known to affect defense-related activities of eastern oyster ameobocytes (Fisher & Newell 1986, Fisher & Tamplin 1988), as is the seasonal reproductive cycle (Fisher et al. 1989, Fisher et al. 1996).

Bivalves do not produce antibodies for specific recognition of antigens, but rely on robust, relatively non-specific cellular and humoral mechanisms to heal wounds and ward off microbial invaders. Bivalve ameobocytes, also called coelomocytes, hemocytes, leukocytes, phagocytes, and blood-cells, are considered key to internal defense because of their ability to phagocytose, encapsulate, and degrade foreign material, including parasites and pathogens (Takatsuki 1934, Wagge 1955, Bang 1973, Narain 1973, Cheng 1975, 1981, 1984, Fisher 1986, Feng 1988, Chu 1988, Chu 2000). Essential to these activities is the mobility of ameobocytes and their capacity to migrate across epithelial barriers (diapédesis). Defense is not the only role of bivalve ameobocytes; they are reported to participate in a variety of other important biologic functions, most notably food digestion, excretion, and shell deposition (Yonge 1928, Wagge 1955, Narain 1973, Cheng 1977, Feng et al. 1977). Each of these roles is undoubtedly affected by both natural and anthropogenic stimuli in the environment.

Field Studies Positively Link Chemical Contaminants and Ameobocyte Activities

Recent investigations in Florida characterized the prevailing responses of oyster defenses, particularly ameobocyte-based de-

fenses, to a spectrum of pollution types and intensities under natural conditions. The approach was intended to provide a "real-world" characterization of multiple factors without regard to independent effects of individual chemicals. Eastern oysters were collected from polluted and unpolluted sites to compare tissue chemical residues and defense activities. Although immunosuppression is a common expectation, the studies revealed a higher level of amoebocyte activities for oysters collected at the more polluted sites. In the first study (Fisher et al. 2000), oysters were collected from 16 heavily-, moderately-, and lightly-contaminated sites in Tampa Bay (Long et al. 1991, Long et al. 1994, McCain et al. 1996). Circulating amoebocytes of oysters at the more contaminated sites exhibited higher numbers and higher locomotory activity (Table 9). Positive associations with these putative defense characteristics were strongest at sites where oysters had high concentrations of metals, particularly copper and zinc, and polycyclic aromatic hydrocarbons (PAH). Based on a preconception that metals were sequestered solely for detoxification and elimination, it was suggested that the presence of high ambient metal concentrations triggered an elevated amoebocyte response to protect the organism. Enhancement of defense activities was believed incidental to detoxification (Fisher et al. 2000).

A subsequent survey (Oliver et al. 2001) explored the geographic extent of this association by examining oysters collected from 22 locations across 5 Florida bays (St. Andrew, Choctawhatchee, Pensacola, Tampa, and Biscayne Bays, Fig. 13). Chemical concentrations and defense factors varied across bays and among sites within a bay. Within-bay comparisons reiterated the finding that oysters inhabiting contaminated sites had higher numbers of circulating amoebocytes, higher percentages of mobile amoebocytes, and higher rates of locomotion. These characteristics were positively associated with site-averaged concentrations of metals, particularly copper, tin, and zinc (Table 10), PAHs, and even with certain polychlorinated biphenyls (PCB). Data analyzed across all five bays also revealed a strong and consistently positive association between tissue chemical concentrations and amoebocyte measurements. These results, corroborating those of the first study, led to a projection that the prevailing effect of environmental mixtures of chemicals on defenses of Florida oysters was enhancement,

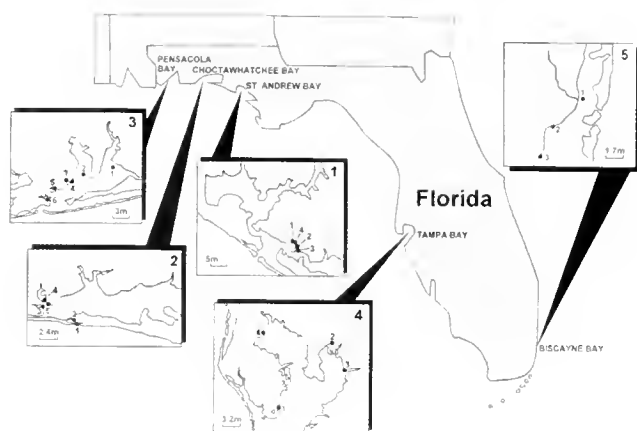

Figure 13. Oyster collection sites (22) from five bays across Florida. Chemicals analyzed from oyster tissues included metals, PAHs, PCBs and pesticides. Measurements on oyster amoebocytes included density (number mL^{-1} hemolymph), percent locomotory and rate of locomotion (Oliver et al. 2001).

rather than suppression, of amoebocyte numbers and defense capabilities.

Technical Constraints and Resolutions

Understanding the prevailing effect of enhanced defenses at contaminated sites was limited by two technical constraints. First, measurements of different amoebocyte activities in both studies were performed as indicators of defense capacity ("putative" defense characteristics), rather than direct measures. Although it is easily accepted that more, and more highly active, amoebocytes should augment the defense response, clear evidence of elevated microbicidal activity would have been profoundly more convincing. Accordingly, a vertebrate procedure to estimate microbial killing by amoebocytes *in vitro* was adapted (Volety et al. 1999). *Vibrio parahaemolyticus*, common bacteria in oysters and coastal environments, were incubated with constant numbers of circulating

TABLE 9.

Summary of results from oysters collected at 16 sites in Tampa Bay, Florida (Fisher et al. 2000). *Top*: Number of significant positive and negative associations ($P < 0.05$) between amoebocyte defense characteristics and various chemicals analyzed from oyster tissues. Defense characteristics include amoebocyte density (number mL^{-1} hemolymph), percent locomotory amoebocytes, and rate of amoebocyte locomotion. Associations were determined by comparison of pooled chemical data from each site (20 oysters) with averages of 20 individuals from the same site. *Bottom*: R-values for copper, tin, and zinc, all exhibiting significant positive associations.

Association	Amoebocyte Density	Percent Locomotory	Rate of Locomotion

Sn	0.665	0.464	0.415
Zn	0.463	—	—

amebocytes. After a challenge period, numbers of surviving bacteria were estimated by a colorimetric assay based on their reduction of tetrazolium dye. This technique, applied in this and other studies (Genthner et al. 1999, Volety & Fisher 2000), provided a direct and more definitive assessment of eastern oyster defense capacity.

The second technical constraint involved the decision to analyze chemical concentrations from a single composite of 20 oysters collected from each site, an experimental compromise necessitated by the need for sufficient tissue to assay a broad array of chemicals. This decision negated the statistical correlation of specific analytes with specific amebocyte characteristics, which were measured independently for each oyster. Chemical concentrations in oysters at the same site are known to be highly variable (see Section II), and a single composite value could not adequately reflect concentrations of an individual.

Deployment Studies in Pensacola Bay Area

To overcome these two technical constraints, a subsequent study measured metals from individual organisms and applied the amebocyte killing assay as a direct estimate of amebocyte defense activity (Oliver et al. 2003). Only two sites in Pensacola Bay were sampled, but they differed markedly in type and magnitude of chemicals present. Chemical analyses were confined to metals and butyltins from individual oysters at each site, which allowed statistical correlation with amebocyte measures from the same oyster. Additional chemicals were analyzed as previously, from a composite. Oysters from one site (Bayou Chico) bore significantly higher concentrations of Cu, Mn, Sn, Zn, butyltins, PAH, and PCB and displayed significantly higher circulating amebocyte numbers and bactericidal activity. These oysters exhibited significantly lower concentrations of Al, Cr, Fe, Ag, Cd, and Hg than oysters from the East Bay site. Statistically-significant correlations were found between defense measurements and specific analytes (Table 11). Corroborating the previous findings, circulating amebocyte numbers and bactericidal activity were positively correlated with Cu, Sn, Zn, total metals, tributyltin, and total PAH.

Although an association between chemicals and defense activities was reasonably established, it was still unknown whether elevated defenses were induced through short-term chemical exposure (acclimation), were selected through survival of defensively-active oysters at chronically contaminated sites (adaptation), or both. An additional study was performed to determine whether short-term exposures would alter amebocyte activity (Fisher et al. 2003). Hatchery-reared oysters were deployed for 12 weeks in the summer at 3 sites in Pensacola Bay, Florida. The sites (Bayou Chico, Bayou Texar, and Santa Rosa Sound, respectively) were heavily-, moderately- and lightly-influenced by anthropogenic discharges. Tissue concentrations of Cu and Zn (Fig. 14) as well as Cr, butyltins, and PAH increased dramatically at Bayou Chico during deployment. Concomitantly, amebocyte number and bactericidal activity were significantly elevated at Bayou Chico. These results, while not excluding adaptation, demonstrated that amebocyte enhancement could be an acclimation response. Positive associations of chemicals with amebocyte number and activity corroborated the earlier studies, but results from a 16-week spring deployment were equivocal, implying that the stimulus, response, or capacity to detect a response was seasonally-dependent or influenced by other environmental factors.

Results from these field studies consistently demonstrated that

TABLE 11.

Correlation analysis between amebocyte characteristics and tissue metal concentrations in individual oysters analyzed by Oliver et al. (2003). Twenty oysters were analyzed from each of two sites ($n = 40$) differing dramatically in chemical contamination. Bacterial killing index is the percent of bacteria (*Vibrio parahaemolyticus*) killed *in vitro* and amebocyte density is the number of amebocytes mL^{-1} hemolymph. Pearson's correlation coefficients are reported as significant at $P < 0.05^*$, significant at $P < 0.01^{**}$, or not significant (ns). Positive correlation coefficients are shown in bold type.

environmental contaminants stimulated, rather than suppressed, amebocyte defense activities. The results portrayed cumulative effects of multiple chemicals under natural environmental conditions, not the effects of individual chemicals that might independently suppress or stimulate amebocytes. The studies did not examine, despite the obvious implication, any mechanistic linkage to oyster disease resistance. However, they established a consistent and defensible relationship between amebocyte numbers and defense activities with tissue concentrations of copper and zinc. These were not the only two analytes associated with elevated defenses but, because of their dominating concentrations in oysters and their physical containment within amebocytes, a possible cause-effect relationship became worthy of consideration.

ANTIMICROBIAL FUNCTIONS OF COPPER AND ZINC

It was reported in Section III that accumulations of copper and zinc in oysters were so extraordinarily high that many investigators believed they exceeded useful amounts (Hiltner & Wichmann 1919, Bodansky 1920, Korrington 1952, Pequegnat et al. 1969, Wolfe 1970a, Simkiss & Mason 1983).

"It seems probable that zinc, as well as copper, can be absorbed and retained in the tissues of the oysters in quantities far in excess of functional requirements, especially in oysters grown in waters badly polluted with metallurgical and factory wastes." (Hiltner & Wichmann 1919, p. 221)

Functions that might be served (e.g., respiratory pigment) (Mendel & Bradley 1905, Prytherch 1934) or enzyme catalysts (Pequegnat et al. 1969), simply did not require the high concentrations accumulated in tissues. Ruddell and Rains (1975) hypothesized that the metals might be used in numerous oyster functions.

Figure 14. Comparison of hatchery oysters at the time of deployment (initial) and after 12 weeks at Bayou Texar, Bayou Chico, and Santa Rosa Sound (SRS), all sites in the Pensacola Bay area (Fisher et al. 2003). Top: Copper and zinc concentrations in oyster tissues normalized to the initial concentrations ($46 \mu\text{g copper g}^{-1}$ and $1230 \mu\text{g zinc g}^{-1}$) show elevated concentrations at Bayou Chico. Bottom left: Ameboeyte densities ($\times 10^6 \text{ mL}^{-1}$ hemolymph) were significantly elevated at Bayou Chico over initial values. Bottom right: Ability to kill bacteria (*Vibrio parahaemolyticus*) under *in vitro* conditions was elevated in ameboeytes from Bayou Chico. Killing index is percent of bacteria killed by a constant number of ameboeytes.

including hydration of CO_2 , maintenance of extracellular and intracellular pH, production or entrapment of free radicals, regulation of redox potentials, or traps for small molecular weight compounds with affinities for zinc or copper. Yet, these roles would be difficult to perform for metals sequestered within ameboeyte granules and, even if true, all these functions combined would probably not require the concentrations that can be accumulated.

This review rekindles a premise of functional roles for high accumulations of copper and zinc. Field studies described in Section IV demonstrated greater ameboeyte numbers, mobility and bactericidal activity in eastern oysters inhabiting sites contaminated with high levels of copper and zinc. In particular, elevation of bactericidal activity implicated a true physiologic function for copper and zinc in oyster defense. Such a role, in fact, had already been proposed, as described below.

Copper and Zinc in Wound Healing

Ruddell (1971) confirmed the observations of Pauley and Sparks (1965) and DesVoigne and Sparks (1968) that green coloration often accompanied the healing of wounds in *C. gigas*. This coloration Ruddell interpreted as an inflammatory response involving copper-laden ameboeytes, an association that had been well established (Section I). In his experiments, Ruddell provoked an inflammatory response by wounding the mantle tissues or implanting excised oyster tissue into an intact mantle cavity. Tracking the tissue changes histologically, he found that copper did, indeed, appear at the site of the wound, first bound within the granules of acidophilic granular ameboeytes (AGA), but later in

extracellular spaces bound to surfaces of muscle, nerve and epithelial tissues near the wound. Copper was subsequently found in granules of basophilic granular ameboeytes (BGA) at the wound site, but not in BGAs distant from the wound site. These observations he interpreted to mean that copper, which was accumulated primarily in AGAs, was released at the site of a wound, distributed to tissues near the wound area, and then recovered into granules of BGAs. From these observations, Ruddell (1971) proposed that copper served as an antimicrobial agent:

"Although it is apparent that copper plays an essential role in the oyster inflammatory response, the function of the copper in the response is not known. One can presume that copper might function to ward off, destroy, or inhibit the growth of potential oyster pathogens." (Ruddell 1971, p. 110)

Ruddell (1971) also hypothesized a similar role for zinc. His evidence indicated that BGAs recruited to the site of a wound underwent swelling and released zinc from their granules. He also noted the release of other constituents, in particular diazo-positive material that he believed was a phenolic substance.

Using both *C. gigas* and *C. virginica*, Ruddell and Rains (1975) formulated a functional role for high accumulations of copper and zinc. Although they understood that zinc- and copper-rich ameboeytes could be used in diverse ways, they believed that a primary role was in response to trauma.

"It would seem probable that oysters do use their basophils and hence, by extension, the large amounts of zinc and copper incorporated in the basophils. Therefore, although oysters may contain very large quantities of zinc and copper, these metals must not be regarded as being stored away in a physiologically inactive form." (Ruddell & Rains, p. 590)

Their studies provided compelling rationale for extracellular killing by copper and zinc, serving in their well-known capacity as "antimetabolites for a diverse number of animal, plant and microbial forms." Direct evidence of microbial killing is lacking, however, even though concentrations of copper and zinc in ameboeytes (see Table 6) seem more than adequate to effect toxic action.

Extracellular Clot Formation

Ruddell's demonstration of extracellular release of copper and zinc led to later research on the formation of extracellular clots. Most organisms have some mechanism to form clots in the hemolymph or blood; clotting is a sequence of complex chemical and physical reactions that results in conversion of fluid (hemolymph or blood plasma) into a coagulum. Clotting in invertebrates, as described by Gregoire (1970), involves the exudation or eruption of blood cells to release granular material into the surrounding fluid. Circular clouds of a granular consistency form around the blood cells, and they eventually develop into "islands of coagulation" formed by networks of granular fibrils. In most early studies, lamellibranch hemolymph was found to lack extracellular clotting. Takatsuki (1934) noted clumping of ameboeytes withdrawn from *O. edulis*, but he did not observe any extracellular clot formation.

"The amoebocytes of the oyster were allowed to stand after being drawn from the body: the mass of amoebocytes did not become jelly-like by coagulation as in the case of crustacean and vertebrate blood, and no fibrin appears in the blood-plasma which remains fluid on standing in the air and even after being heated." (Takatsuki 1934, p. 402)

Eastern oysters became the first, and may well be the only, bivalve known to exhibit such a response (Naram 1973). Frederick B. Bang (1961) described clotting in eastern oysters as an extracellular, finely-granular "gel" that occurred around aggregates (clumps) of amoebocytes (Fig. 15). Clots were observable on glass slides under phase-contrast microscopy within 30 min of hemolymph withdrawal, and they resembled clots formed naturally in the hemolymph vessels of traumatized oysters. He noted that these clots could trap and immobilize bacteria, presumably making the bacteria more susceptible to phagocytosis.

"It seems to have a real rôle in the repair of traumatized tissue, for: 1) it was found already developing in small cellular clots taken directly from the heart; 2) it occurred predominantly around clumps of cells; 3) bacteria were immobilized by its development . . . and, 4) it was obtained both immediately after opening an oyster and from some preparations which had been on the half shell as long as 24 h. Its possible relation to cycles of feeding by the amoebocytes is unknown." (Bang 1961, p. 61)

Copper and Zinc Initiate Extracellular Clot Formation

Bang (1961) felt that the extracellular gel in eastern oysters may have originated from extrusions of the cellular granules of the amoebocytes (degranulation), a process previously described for arthropods (Gregoire 1970). It was not until a decade later that one of Bang's doctoral students, Robert S. Brown, followed up on this hypothesis. He noted that extracellular clots would sometimes

form when whole hemolymph or plasma was added to glass slides treated with alconox detergent (R. S. Brown, personal communication). Subsequently, he found that other detergents and a variety of other substances, including bases, alcohols, copper, and zinc, would also cause extracellular clotting (Fig. 16). Recognizing that copper and zinc were used in biochemical separation methods to precipitate proteins, Brown combined the work of Bang (1961) and Ruddell (1971) to forge his dissertation hypothesis that copper and zinc released from amoebocyte granules precipitated hemolymph plasma proteins to form extracellular clots (Brown 1975). To test his hypothesis, Brown investigated 3 basic suppositions; (1) that oyster amoebocytes were the source of the clot-promoting substance, (2) that copper and zinc were released from amoebocytes into the plasma, and (3) that copper and zinc produced clots in plasma by precipitating proteins.

Using a variety of microscopic and analytical tools, Brown (1975) was able to support each of the suppositions. He reiterated Bang's finding that extracellular clots were always associated with

Figure 15. Eastern oyster amoebocytes and extracellular clotting of hemolymph shown as coarse, granular areas (phase-contrast microscopy, $\times 1,664$). Reproduced from a duplicate published in Brown (1975; Fig. 11 with author's permission) of the first published micrograph of extracellular clotting in bivalves by Frederick B. Bang (1961; Fig. 6, with permission of the *Biological Bulletin*).

Figure 16. Eastern oyster amoebocyte aggregates with extracellular clots forming a network around the cells ($\times 480$). Top: Clot formed immediately after addition of 0.1M NaOH to whole hemolymph. Bottom: Clots formed immediately after addition of 0.5% detergent to whole hemolymph. (Reproduced from Brown 1975; Fig. 17 with permission of the author).

amebocyte aggregates (Fig. 17) and would not form in hemolymph if amebocytes were removed. Clots would form if amebocytes were added back to cell-free hemolymph, even if the amebocytes had been fixed with glutaraldehyde, or were frozen, boiled and extracted before reintroduction. He verified for *C. virginica* the earlier evidence (Ruddell 1971) that *C. gigas* amebocytes sequestered copper and zinc (see Figs. 6 and 7) and that they were retained in amebocyte granules (see Figs. 8 and 9). He used a combination of techniques to verify that high concentrations of copper and zinc were excluded from agranular regions of the amebocytes (See Fig. 10).

To provide some evidence that amebocytes could release copper and zinc from the granules, Brown (1975) presented electron microscopic evidence that independent amebocytes were highly granulated, whereas those amebocytes in aggregates were either completely degranulated, in the process of degranulation, or in some cases, undergoing cytolysis (Fig. 18). He believed degranulation provided a mechanism for release of copper and zinc into the hemolymph. He also revealed that extracellular clots had a relatively high staining affinity (Fig. 19) and high concentrations of copper ($356 \mu\text{g g}^{-1}$, dry weight) and zinc ($10,571 \mu\text{g g}^{-1}$); these were substantial amounts, particularly in comparison to the minute quantities found in clot-free plasma (copper $< 0.2 \mu\text{g mL}^{-1}$ and zinc $< 10 \mu\text{g mL}^{-1}$).

Finally, Brown (1975) demonstrated that addition of either Cu-acetate or Zn-acetate to cell-free oyster plasma created precipitates that were indistinguishable from *in vitro* clotting (Fig. 20). Precipitation required a minimum of either $0.6 \mu\text{g Cu mL}^{-1}$ or $0.15 \mu\text{g Zn mL}^{-1}$ hemolymph and, as expected, precipitation dramatically reduced the concentration of plasma proteins. When plasma was first deproteinized with trichloroacetic acid, no amount of copper or zinc would cause precipitation. Similarly, if copper were added to zinc-treated plasma, no further precipitation resulted. Boiling of the plasma did not influence the ability of copper or zinc to effect precipitation, leading to Brown's conviction that extracellular clot formation was a non-enzymatic chemical action. He found that ethylenediaminetetra-acetic acid (EDTA) and hydro-

Figure 18. Transmission electron micrograph of a peripheral edge of aggregated eastern oyster amebocytes ($\times 10,000$). Although not visible in this preparation, an extracellular clot was formed from this aggregate. Amebocytes appear agranular or in the process of degranulation (arrows). Some cells appear to be lysed (asterisk). (Reproduced from Brown 1975; Fig. 14 with permission of the author).

chloric acid (HCl), both known to disperse metal-protein precipitates, also dispersed extracellular clots.

In all, Brown's (1975) data indicated that copper and zinc from amebocytes could interact with proteins in the hemolymph *via* a non-enzymatic, inorganic reaction to form locally-restricted precipitations, or clots, consisting of calcium and magnesium hydroxide, phosphates and carbonates. There may be other constituents released simultaneously by the amebocytes, such as the phenols described by Ruddell (1971), that may also play a role in clot formation. Phenoloxidase is a constituent of the prophenoloxidase clotting system in crustaceans (Söderhäll 1982, Söderhäll et al. 1994) that is believed to provide melanin for encapsulation of invading microorganisms. Although not linked to a clotting mechanism, phenoloxidase activity has also been reported in bivalves (Coles & Pipe 1994, Asokan et al. 1997, Carballal et al. 1997, Deaton & Dankert 1998, Peters & Raftos 2002).

Brown (1975) did not analyze the form of copper and zinc in the granules of amebocytes or in the extracellular clots. The work of Coombs (1972) led George et al. (1978) to conclude that granules contained copper sulfide and zinc phosphate. Metal speciation may be important because it could control the pH of material released from the amebocyte granules. Either high or low pH could contribute to release of metals from the granules and protein precipitation in the hemolymph. Beaven and Paynter (1999) have shown that phagosomes (see below) become highly acidified after fusion with lysosomal granules.

Intracellular Microbicidal Potential of Copper and Zinc

Ruddell & Rains (1975) confined their speculations to the extracellular microbicidal capacity of copper and zinc in wound healing. However, the possibility that these metals participate in intracellular killing by amebocytes is equally compelling. Metchnikoff

Figure 17. Electron micrograph ($\times 23,500$) of an extracellular clot (ECC), which appears as a finely granular material between the juncture of five aggregated amebocytes taken from a mantle wound of an eastern oyster. (Reproduced from Brown 1975; Fig. 13 with permission of the author).

Figure 19. Histochemical demonstration of copper and zinc in extracellular clots of eastern oyster plasma. (1891) brought attention to evidence that vertebrate and invertebrate amoebocytes possess phagocytic ability. A complex process, phagocytosis requires that amoebocytes recognize, locate, ingest, and either transport or digest foreign particles. In eastern oysters, as in other bivalves, phagocytosis is considered critical to both nutrition and internal defense (Cheng 1977, Feng et al. 1977). To provide nutrient, amoebocytes migrate into the digestive tract to engulf particles of food, digest them, and then migrate into the tissues and hemolymph to release nutrient (usually as glycogen) to metabolizing cells. Yonge (1937, 1946), among others, believed this to be the primary nutritional pathway for oysters. Using a similar process, amoebocytes can capture unwanted particles and microorganisms (parasites and pathogens) in the mucus and hemolymph to prevent microbial growth in the soft tissues. If the phagocytosed material has no nutritive value, it can be eliminated through feces or pseudofeces by amoebocyte exomigration (see

PRECIPITATION OF OYSTER PLASMA PROTEIN BY COPPER AND ZINC

Figure 20. Demonstration by Brown (1975) of precipitation of eastern oyster hemolymph plasma by copper and zinc. A clot-like precipitate formed in cell-free plasma immediately after addition of copper or zinc, whereas no precipitate formed if either the plasma or the metal was absent. Precipitation of plasma by one agent eliminated further precipitation by later addition of other agents. (Reproduced from Brown 1975; Fig. 31 with permission of the author).

Section II). It has been postulated that phagocytosis was originally a nutrient-acquiring process that eventually evolved into a defensive capability (Cheng 1975, Feng et al. 1977).

Professor Leslie A. Stauber (1950) initiated the first of many studies that characterized phagocytosis in marine bivalves when he traced the fate and disposition of injected india ink particles in *C. virginica*. Three investigators, Sung Y. Feng, Marennes R. Tripp and Thomas C. Cheng, followed Stauber's initiative with innumerable experiments and cogent descriptions of bivalve internal defense, often using eastern oysters as a model system (see Cheng 1983). Iterative updates on their progress were provided by Cheng (e.g., Cheng 1967, 1975, 1981, 1984, 1996). Combined, these studies have detailed the fates of a diverse array of foreign particles and microorganisms in oysters and characterized the process of phagocytosis (e.g., Stauber 1950, Stauber 1961, S. Y. Feng 1958, 1966, 1967, 1988, Tripp 1958, 1960, 1970, J. S. Feng 1966, Tripp & Kent 1967, Acton et al. 1969, Fries & Tripp 1970, Feng et al. 1971, 1977, Cheng & Cali 1974, Foley & Cheng 1975, 1977, Cheng & Rudo 1976, Renwantz et al. 1979, Hinsch & Hunte 1990). Most living microorganisms are killed upon ingestion by phagocytic amoebocytes, including viral particles (J. S. Feng 1966, Fries & Tripp 1970) bacteria, phytoplankton (e.g., *Navicula ostreocaria*), and metazoans. But some microorganisms are able to survive and even multiply within the phagosomes. Of particular interest for eastern oysters is the apparent ability of *Perkinsus marinus*, a devastating oyster pathogen, to grow and multiply within host amoebocytes (Mackin 1951).

Ingestion, or endocytosis, of microorganisms by eastern oyster amoebocytes reportedly can occur in three ways: some microbes adhere to the amoebocyte filopodia (Bang 1961), some are taken into funnel-shaped pseudopods (Renwantz et al. 1979), and some are enveloped in a vesicle on the amoebocyte surface (Cheng 1975). Regardless of the path of entry, the targeted microorganism is captured and drawn into a cytoplasmic invagination (Fig. 21) that encircles it with concentric lamellae to form a "phagosome" (Cheng 1975). Digestion of the microbe begins in this primary phagosome but, at least for eastern oysters, can be transferred to, or evolve into a secondary phagosome which has an electron-dense

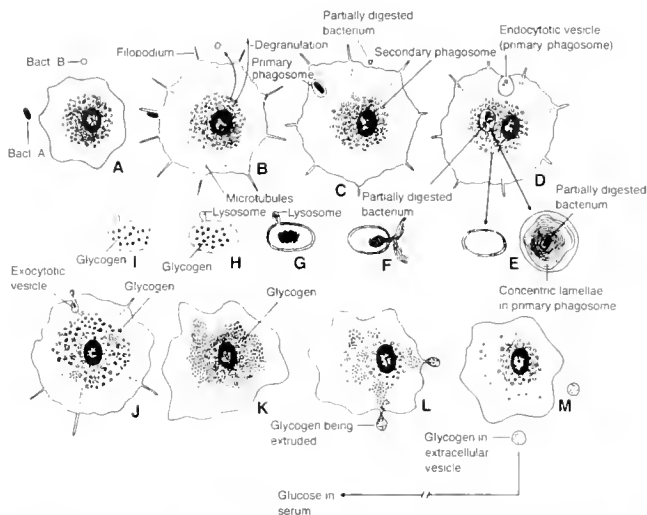

Figure 21. Description of phagocytosis of bacteria by eastern oyster amebocytes as described by Cheng (1975). Granules participate in both intracellular and extracellular degradation. Intracellular digestion occurs after a bacterium is isolated in a phagosome, then exposed to degrading enzymes released when the phagosome fuses with cytoplasmic granules (lysosomes). This can result in the eventual release of glycogen as a nutritional product. Extracellular degradation of bacteria occurs when amebocytes “degranulate” or release the hydrolytic enzymes of the lysosomes outside the cell. (Diagram from Cheng 1996; Fig. 11 with permission of Maryland Sea Grant).

outer surface comprised of a thick outer wall. Lysosomes, which are membrane-lined organelles containing acid hydrolases, have been observed to fuse with secondary phagosomes (Cheng 1975), and may fuse with primary phagosomes as well (Cheng 1996). Fusion of lysosomes with phagosomes is believed to expose the microorganism to degrading lysosomal enzymes. The fused organelle is sometimes called a “phagolysosome”. Fusion with a lysosome results in relatively rapid acidification of the phagosome (Beaven & Paynter 1999).

Both granular and agranular (hyaline) amebocytes have been found capable of phagocytosis, but granular forms are recognized to be much more active. Foley and Cheng (1975) found over 80% of the granular amebocytes in *C. virginica* to phagocytose *Staphylococcus aureus* and *Escherichia coli* compared with less than 20% of hyaline amebocytes. With the exception of Ruddell (1971), who may not have included degranulated cells (fibrocytes) in his estimates (see Cheng 1981), it is generally maintained that granular amebocytes are more abundant and more actively phagocytic in oysters than agranular amebocytes. This may be because granules play a critical role in the phagocytic process. In fact, granularity and phagocytic activity may be tightly linked; Beaven and Paynter (1999) discovered that the number of visible granules in eastern oyster amebocytes declined as phagocytosis proceeded. It could be inferred that highly granular amebocytes are avidly phagocytic, but lose their potential as more granules fuse with phagosomes.

The amebocyte granules that contain copper and zinc are morphologically indistinguishable from lysosomes, and there is little reason to believe that they are not the same. Ruddell (1971) called the copper and zinc granules “lysosomal derivatives”, but did not elaborate on similarities or differences. From the results of Brown (1975), it seems that virtually every granule in the eastern oyster amebocyte contains some copper or zinc (see Figures 6–9). There

has been some suggestion that granules and lysosomes in eastern oysters differ morphologically (Feng et al. 1971, Cheng 1975), but distinctions between the two are vague. Yoshino and Cheng (1976) demonstrated through cytochemistry and electron microscopy that the granules in amebocytes of *Merccenaria mercenaria* were lysosomes, serving as storage organelles for hydrolytic acids. Foley and Cheng (1977) showed that lysosomes can be stimulated to move to the surface of the amebocyte and expel their contents (Fig. 22), a process that resembles, or is identical to the degranulation process described by both Ruddell (1971) and Brown (1975) for metal-containing amebocyte granules. It can be postulated from these observations that the copper- and zinc-bearing granules in eastern oysters are either lysosomes or closely-related structures.

It is possible to hypothesize a role for copper and zinc in intracellular microbiocidal activity. When phagosomes fuse with cytoplasmic granules, the captured microorganisms are exposed to very high, and likely toxic, concentrations of metals and hydrolytic enzymes. Unlike the case for extracellular killing, metals used in intracellular killing remain inside the cytoplasm. If the phagosome breaks down, as has been described for the release of glycogen granules in nutritive digestion, the metals could be recovered by newly-formed granules.

Extracellular Toxicity to Encapsulated Microorganisms

A similar extrapolation might be drawn for the role of copper and zinc in amebocyte action against larger microorganisms (i.e., parasites that have been encapsulated). Encapsulation is the simultaneous envelopment of relatively large foreign bodies by numerous amebocytes (Fig. 23). The foreign body is usually too large for a single amebocyte to ingest; nonetheless, encapsulation may be the consequence of independent attempts by many amebocytes to phagocytose the invader (Cheng & Rifkin 1970). The cells become flattened against the surface of the foreign body and ultimately cut it off from host tissues.

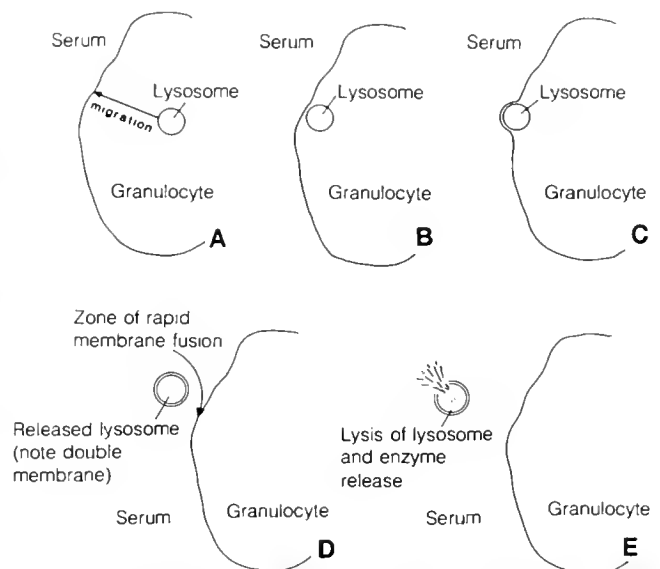

Figure 22. Schematic diagrams of degranulation, or release of lysosomes from a bivalve granulocyte. (A–C) Lysosomes migrate to and protrude through the plasma membrane. (D) Double-membraned lysosomes are exocytosed from the granulocyte and eventually lyse (E) to release lysosomal enzymes. It is likely that the same mechanism releases copper and zinc from amebocyte granules. (Figure from Cheng 1996, Fig. 15 with permission of Maryland Sea Grant).

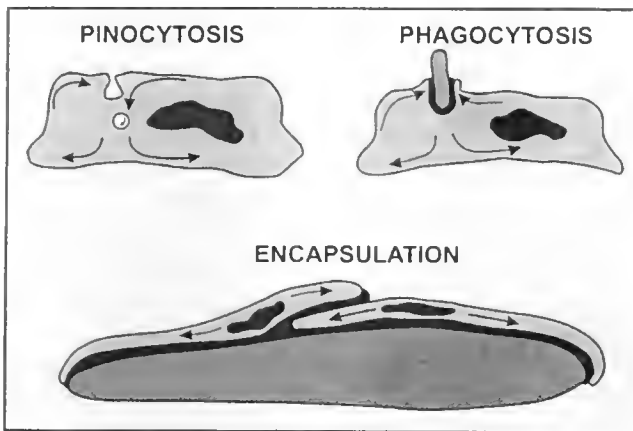

Figure 23. Amoebocytes can respond to foreign objects in three ways: (1) *pinocytosis*, or cell-drinking, is a means to uptake small or dissolved particles and fluid; (2) *phagocytosis*, or cell-eating, is a means to take up larger particles; (3) *encapsulation* occurs when the foreign object is too large for a single amoebocyte to phagocytose. Bang (1973) suggested that pinocytosis involved ingestion without recognition, encapsulation involved recognition without ingestion, and phagocytosis involved both recognition and ingestion. (Graphic redrawn from Bang 1973, Fig. 2).

It is not unlikely, assuming that encapsulation is an attempt at phagocytosis, that encapsulating amoebocytes degranulate while encompassing the intruder. As noted by Cheng (1981).

"... external contact with certain foreign substances will result in hypersynthesis of intracellular lysosomal enzymes which are released from haemocytes into the serum where digestion of the foreign material, such as bacteria, is initiated. The release of enzymes is effected by what has been termed degranulation (Foley and Cheng, 1977), a process involving the migration of lysosomes to the surface of the cell where the enclosed enzymes are discharged." (Cheng 1981, p. 286)

Cheng et al. (1975) demonstrated the extracellular release of lysozyme from lysosomes during phagocytosis by *Mercenaria mercenaria* amoebocytes. Similarly, McDade and Tripp (1967) demonstrated the presence of lysozyme in hemolymph of eastern oysters. Extracellular release of copper and zinc at the site of a wound (Ruddell 1971) is presumably a consequence of amoebocyte degranulation, as is copper-plating of a "well-polished steel knife" (Galtsoff 1964, p. 388). If metals and hydrolytic enzymes are expelled onto the surface of the invader, then the process of encapsulation attains a dual objective of both isolating and debilitating the invader.

Rationale for High Accumulations of Copper and Zinc

Evidence has been presented that copper and zinc serve antimicrobial functions in eastern oysters, yet it is not immediately obvious why such high accumulations are needed. Brown (1975), for example, estimated that the amounts of copper and zinc contained in eastern oyster amoebocytes was much greater than thresholds necessary to form extracellular clots. Confounding the issue is the fact that living, healthy oysters exhibit widely varying tissue concentrations. The best explanation may simply be that higher concentrations have the capacity to generate a larger clot, or marshal stronger microbicidal action against phytoplankton, bacteria, and viruses. This increased capacity provides a competitive advantage to oysters with higher accumulated concentrations. Perhaps equally important, high accumulations may afford oysters

greater flexibility in realizing this advantage. Amoebocytes are highly mobile and can move across epithelial barriers to virtually any compartment of the oyster (diapedesis). They may, however, be limited in their ability to reach a wound quickly (or an algal cell needed for nutrition) and their movement may leave other areas of the oyster unprotected (or unexploited). High accumulations of copper and zinc, combined with the requisite high numbers and high activity of amoebocytes, provide the oyster a robust, distributed antimicrobial capacity that allows quick responses to frequent or repeated challenges and opportunities throughout the organism.

HYPOTHESES AND RAMIFICATIONS OF AN ALTERNATIVE FRAMEWORK

Numerous independent investigations on metals in eastern oysters have been reviewed to establish that copper and zinc, if not other terrestrial elements, are actively captured and retained for physiologic purposes. This contradicts a historical perception that high accumulations are merely part of a process to detoxify and eliminate the metals. Copper and zinc are physically associated with amoebocytes, so any physiologic role is likely related to amoebocyte functions. Evidence presented here links copper and zinc to antimicrobial functions of amoebocytes in defense and nutrition. A separate report (Fisher 2004) presents evidence of a role for terrestrial metals in shell deposition, which is facilitated by amoebocytes. The findings contradict a tendency to regard copper, zinc, and other metals as unnecessary, if not undesirable, oyster constituents. Introduced through this review is a corollary proposition that oyster success and distribution in near-coastal areas, even at seemingly polluted locations, stems from a dependency on terrestrial elements. These proposals arise from the cumulative interpretations of many scientific contributions, and generate an alternative framework for understanding issues that range from mechanisms of amoebocyte function to coastal distribution of eastern oyster populations. There are numerous considerations that bear on the legitimacy of this alternative framework, some supported more than others by existing evidence, but all deserving at least some corroborative research. These considerations are listed below in a series of broad, umbrella hypotheses (H1–H6).

Eastern Oyster Adults Actively Accumulate Terrestrial Copper and Zinc

(H1) The most consistent information amassed over several years and numerous studies is that accumulation of copper and zinc is extremely high in eastern oysters, a status supported by their ability to concentrate the metals from low ambient concentrations and retain them longer than other metals despite availability of an efficient elimination mechanism. Long retention may mean that copper and zinc are transferred from old to young amoebocytes by phagocytosis or apoptosis. Active assimilation and accumulation of the metals signifies a cost to oyster energetics. Accumulations of copper and zinc, rare in marine environments, represent quantities acquired from terrestrial watersheds. This factor may limit oyster distribution to estuarine and near-coastal locations.

Copper and Zinc are Sequestered in Membrane-lined Granules of Amoebocytes

(H2) There can be little doubt that copper and zinc are retained primarily, if not exclusively, in oyster amoebocytes. Metals have been reported in amoebocytes from microscopic observations (e.g., green oysters), various histologic preparations, and electron mi-

croscopic imaging techniques. Storage in amoebocytes provides a transport mechanism to quickly distribute the metals to virtually any site in the organism. Copper and zinc are sequestered in membrane-lined granules in the amoebocyte cytoplasm at high concentrations. Sequestration shields vulnerable tissues from exposure and is the primary reason that eastern oysters can safely accumulate high tissue concentrations. Acquisition of metals by the granules probably occurs by phagocytosis of metal-laden mucus (see later) or food particles (e.g., phytoplankton and bacteria). The chemical speciation of metals in the granules allows their discharge and bioavailability upon degranulation or fusion with phagosomes.

Ambient Dissolved Copper and Zinc are Bound in Mantle-cavity Mucus

(H3) Oysters assimilate copper and zinc from ambient water or food into protective amoebocyte granules without prolonged or excessive exposure to unprotected tissues. Chemical properties of mucus ensure strong binding of any cations entering the oyster mantle cavity and prevent their absorption into tissues. Binding with mucus also provides an efficient elimination mechanism for unwanted metals; mucus accumulates in the pseudofeces, which is passed out of the body. Uptake of metals, on the other hand, may be achieved in a controlled manner by amoebocyte phagocytosis of mucus and particles bound in mucus. Phagocytic activity captures copper and zinc in membrane-lined phagosomes, vesicles formed by invaginations of the cell membrane. These vesicles may ultimately form metal-containing granules. Embryo and larval stages, without the copious mucus production of adults, are vulnerable to water-borne copper and zinc toxicity.

Copper and Zinc Accumulation Depends on Availability of Amoebocytes

(H4) Amoebocytes are highly phagocytic and can migrate throughout the alimentary tract and mantle cavity to acquire copper and zinc from food or mucus. Safe accumulation of the metals, however, depends on the availability of amoebocytes with metal-carrying capacity. Amounts of metal that can be stored in an amoebocyte are presumably constrained by its size, its capacity to form and retain granules, and the metal-carrying capacity of the granules. Whenever existing amoebocytes are saturated, additional uptake from the environment requires additional amoebocytes. Uptake by eastern oysters is thus dependent on the rate of amoebocyte proliferation or recruitment. Specific amoebocyte cell types may be recruited based on the metal present (i.e., BGA for copper and AGA for zinc). Higher numbers of amoebocytes increase the oysters' capacity to accumulate metals.

Degranulation Releases Copper and Zinc from Amoebocyte Granules

(H5) In a process diametric to endocytosis, lysosomal membranes fuse with the outer cell membrane to discharge lysozyme into extracellular spaces (degranulation). Lysosomal granules also fuse with cytoplasmic phagosomes to discharge lysozyme into phagolysosomes for killing or digesting trapped microorganisms. Amoebocyte granules that contain high concentrations of copper and zinc are similar, if not identical, to lysosomal granules. Copper and zinc, which may occur in all granules, are discharged simultaneously with lysosomal enzymes into extracellular spaces or phagolysosomes.

Copper and Zinc Provide Extracellular and Intracellular Antimicrobial Activity

(H6) Antimicrobial activities of copper and zinc include clotting of hemolymph and both intracellular and extracellular killing

of microorganisms. For intracellular killing, granules fuse with phagosomes to discharge hydrolytic enzymes and toxic concentrations of copper and zinc, which may act in concert. Toxic metals released intracellularly are excluded from vulnerable host tissues and simultaneously retained for future use. For extracellular killing, a burst of either metal during degranulation will affect invading microbes without severe damage to surrounding tissues. The high mobility and flexible morphology of amoebocytes allows degranulation to occur with relative precision at wound sites, possibly even directed at individual microorganisms. Metals are recouped to protect nearby tissues from prolonged exposure and for re-use. Extracellular discharge of copper and zinc might also provide antimicrobial activity against encapsulated microorganisms. Copper and zinc released from granules into the hemolymph precipitate proteins and generate a clot. Clotting provides a granular net to capture and immobilize bacteria and stem the flow of plasma (hemostasis). Amoebocyte clumping, or aggregation, is also a factor in hemostasis and occurs simultaneously with extracellular clot formation.

Potential Ramifications of an Alternative Framework

Anticipating that some of the considerations above are ultimately justified by direct evidence, it is worth considering potential ramifications. The most consequential aspect is the influence of copper and zinc on amoebocyte antimicrobial activity. Antimicrobial activity of amoebocytes in defense and nutritional functions has been accepted for eastern oysters, if not most bivalves, for many years (Tripp 1960, Stauber 1961, Feng 1967, 1988, Narain 1973, Anderson 1975, Cheng 1975, 1981, 1996, Fisher 1986). Some early investigators, particularly Yonge (1926, 1937, 1946), believed that amoebocytes were largely responsible for digestion of foods entering the alimentary tract. Although this emphasis has been disputed, amoebocyte participation in nutrition is widely accepted (Takatsuki 1934, Wagge 1955, Owen 1966, Purchon 1968, Narain 1973, Cheng 1975, 1977, Feng et al. 1977).

One of the greatest concerns for fisheries managers over the last 50 years has been diseases caused by 2 protozoans, *Perkinsus marinus* and *Haplosporidium nelsoni*. Host defenses against these two diseases are not well characterized, but it seems that both agents may be susceptible, at least under some conditions, to phagocytosis by oyster amoebocytes (Burreson et al. 1988, Ford & Kanaley 1988, Scro & Ford 1990, Anderson 1996, Volety & Fisher 2000). Both diseases are severe at high salinity locations (Andrews 1988, Andrews & Ray 1988, Ford & Haskin 1988, Haskin & Andrews 1988, Ford 1996, Soniat 1996) and disease intensity can be reduced with low salinity (Sprague et al. 1969, Ford 1985, Ford & Haskin 1988, Chu & Greene 1989, Chu et al. 1993, La Peyre et al. 2003). Hence, the potential enhancement of defenses by copper, zinc, or other terrestrial elements provided by freshwater inflow could be relevant to control of disease.

Also of great concern to the oyster fishery is contamination of commercial oysters with human pathogens such as *Vibrio parahaemolyticus*, *V. vulnificus*, and *V. cholerae* (Kelly & Arcisz 1954, Blake et al. 1979, 1980, Pavia et al. 1987, Bernard 1989, Daniels et al. 1999). Elimination of bacteria from oyster tissues (depuration) is at least partly achieved through phagocytic action of amoebocytes (Rodrick & Ulrich 1984). The ability of oysters to successfully eliminate specific microorganisms partly depends on the species; *Vibrio vulnificus*, for example, is much more persistent in oysters than fecal pollutants such as *Escherichia coli* and *Salmo-*

nella (Perkins et al. 1980, Richards 1988, Jones et al. 1991, Tamplin & Capers 1992). Such persistence may depend on whether the bacteria have light or heavy mucopolysaccharide coats that mask the bacteria from amoebocyte recognition (Harris-Young et al. 1993, 1995, Genthner et al. 1999, Volety et al. 2001). The significantly higher *in vitro* capacity of amoebocytes of oysters from copper- and zinc-contaminated sites to kill *V. parahaemolyticus* (Fisher et al. 2003, Oliver et al. 2003) supports the seemingly ironic speculation that elevated accumulations of copper and zinc in oyster amoebocytes will reduce human health risks.

Studies of chemical influences on oyster defense processes have often demonstrated variable results. Perplexing is the fact that eastern oysters are known to thrive at some highly-polluted sites (Abbe & Sanders 1986). A few studies have linked chemical exposure of eastern oysters with higher prevalence or intensity of infectious disease (Winstead & Couch 1988, Chu & Hale 1994, Anderson et al. 1996, 1998, Fisher et al. 1999), but have never linked vulnerability to any particular defense mechanism (Oliver & Fisher 1999). Some studies have examined effects of individual chemicals on defense mechanisms of amoebocytes (Cheng & Sullivan 1984, Cheng 1988a, Cheng 1988b, Larson et al. 1989, Fisher et al. 1990, Alvarez et al. 1991, Alvarez & Friedl 1992, Anderson et al. 1992, 1994, 1997, 1998, Sami et al. 1992, 1993, Baier-Anderson & Anderson 1997) and found both suppression and stimulation of defense responses (Baier-Anderson & Anderson 2000). Several studies have exposed amoebocytes to chemicals *in vitro*, providing direct contact that may never occur if, under natural conditions, the chemicals are first bound to mucus. Studies of potential immunomodulation are complicated by the fact that chemical mixtures vary from location-to-location. Because each different chemical can elicit a different type and degree of response, it has been almost impossible to anticipate which response would predominate. The field surveys described in Section IV demonstrated enhanced activity at sites with high copper and zinc concentrations, apparently overwhelming effects of any other chemicals. The results provide a novel focus, tissue concentrations of copper and zinc, for comparing defense activities in eastern oysters.

The close association of copper and zinc accumulations with amoebocyte number leads to a speculation that their availability in the ambient environment may lead to proliferation of amoebocytes. Whereas highly conjectural, the significance of this would be extraordinary. Metal stimulation of amoebocyte proliferation might parallel vertebrate immune responses that rely on antigen recognition and binding for lymphocyte proliferation. There is a possibility that increased exposure to only one metal might differentially stimulate recruitment of different amoebocyte types (AGA for copper and BGA for zinc), just as antibody-specific cells are generated by vertebrate systems. Vertebrate studies have demonstrated numerous adverse effects of copper deficiency, including reduced bactericidal activity of neutrophils, decreased macrophage activity, reduced proliferation and activity of B and T lymphocytes, and impaired cell-mediated immunity (see Kramer & Johnson 1992 for review). In fact, deficiencies in copper, zinc, and iron are all recognized to alter immunocompetence in humans and other vertebrates (Sherman 1992).

Currently, we know very little of amoebocyte proliferation in bivalves (Narain 1973). Cuénot (1891) suggested that amoebocytes might originate from special lymph glands at the base of the gills, and subsequent investigators have suggested alternate sites. Wagge (1955) and others believed that new cells were mitotically generated from existing amoebocytes. Stauber (1950) disagreed because

"of the many phagocytes examined, only one has been observed in mitosis" (p. 233). Ruddell (1971) also found only a few granular amoebocytes undergoing mitosis in histologic sections. However, Feng et al. (1977), in their studies of *C. gigas*, encountered binucleated granular amoebocytes and amoebocytes with centrioles "fairly frequently" (p. 61). They felt that Ruddell's (1971) observations might have been peculiar to activities of wound repair. If true that metals are responsible for stimulating mitotic activity, then different amounts available to oysters might well account for discrepancies in the number of mitotic amoebocytes observed in different studies.

There is an alternate possibility that "dormant" amoebocytes are activated by the presence of ambient copper. Prytherch (1934) found copper activated the pigment spot cells in mature eastern oyster larvae. Quiescent, or at least immobile until addition of copper, the cells were found to disaggregate and migrate into the hemolymph to become the first circulating amoebocytes. This "catalytic" action of copper (Prytherch 1934, p. 83) concurrently initiated larval metamorphosis. *In vitro* studies have also shown that reconstitution of cation-depleted media with seawater will initiate disaggregation and migration of adult oyster amoebocytes (Fisher & Newell 1986). Mobilization of amoebocytes has been further implied by the consistent finding of higher numbers of highly-locomotory amoebocytes from oysters collected at metal-polluted sites (Section IV). Greater locomotory activity may account for higher numbers of amoebocytes observed in hemolymph circulation. A mechanism for amoebocyte activation by copper has not been investigated, but catalytic action of copper on oxidation of glutathione has been suggested to increase cell respiration (Prytherch 1934).

The distribution of eastern oysters throughout the Gulf of Mexico and along the Atlantic coast is determined by their ability to survive and reproduce in different environmental conditions. Several have proposed that the distribution of eastern oysters is dependent on freshwater inflow because of the low and variable salinities that hinder parasite growth and high-salinity predators. Low-salinity protection from both parasites and predators has been applied in the development of a "Habitat Suitability Index" for oyster (Cake 1983, Soniat & Brody 1988). However, there is ample evidence that oysters are also successful in high-salinity environments (Beaven 1955, Lunz 1955, J.R. Nelson 1955), so an alternative reason may exist. One rationale is the availability of elements, particularly copper and zinc, from land-based sources. Terrestrial elements are carried by freshwater runoff into bays and estuaries (Reidel et al. 1995, 1998), greater volumes of water carrying them further into the receiving waters. If this dependence is found credible, then the coastal distribution of eastern oysters may be driven by a need for terrestrial elements that play critical roles in oyster physiology, including defense and nutrition (this review), shell deposition (Fisher 2004) and larval setting and metamorphosis (Prytherch 1934).

The investigations reviewed here varied widely in scope, purpose, and content. Consequently, several caveats are required. First, portions of the information reviewed may not have been intended for the purposes to which they have been applied. Even so, the pivotal studies seem well within the perceived intentions of the investigators. Although information was considered from research on several oyster species (particularly *C. virginica*, *C. gigas*, and *O. edulis*), the proposed function in defense is intended only for *C. virginica*. Adequate evidence to compare metal accumulation, adult avoidance of toxicity, and retention of accumulated metals among different oyster species was lacking. Similarly, the

review has emphasized, and is limited to, the fates and effects of copper and zinc. This focus stems from the high concentrations found in *C. virginica* and the nearly exclusive retention of these metals within the amoebocytes. Other reviewers might have included tin (Orton 1923), manganese or iron (Galtsoff 1953, 1964) for consideration. These elements may serve physiologic roles similar to copper and zinc, but this is neither proposed nor defended here. Finally, because issues were wide-ranging, review of material for any specific topic has not been comprehensive. Many studies, such as those showing sublethal effects of copper or zinc exposure were not included (e.g., Cheng 1988a, 1988b, Larson et al. 1989, Anderson et al. 1994, Roesijadi 1994, Ringwood et al. 1998, Butler and Roesijadi 2001). Nor were studies depicting environmental effects on bioavailability of metals (e.g., Zamuda & Sunda 1982, Wright & Zamuda 1987, Knezovich 1994), even though this topic is clearly relevant to the subject. Despite the caveats and selective focus, the evidence presented here supports a compelling image of copper and zinc as elements highly valued, if not fundamental, for oyster defense and nutrition. Such a perspective, in spite of the obvious need for testing and validation,

provokes a need to re-evaluate many biologic, environmental, and resource issues that may be affected.

ACKNOWLEDGMENTS

Florida field survey data were obtained through the combined efforts of my colleagues, Leah M. Oliver and James T. Winstead, to whom I am grateful for many collaborations over the last decade. Thanks are also due our collaborators Edward R. Long, Aswani K. Volety, Fred J. Genthner, and Becky L. Hemmer. I am indebted to Dr. Robert S. Brown, who graciously provided both insight and material from his unpublished dissertation at Johns Hopkins University. Library material was assembled with the assistance of Sonya Doten and Liz Pinnell, and numerous graphics rendered by Stephen Embry. I am indebted to P. Chapman, W. Davis, J. Fournie, L. DiMichaef, D. Shepard and C. Walker for meaningful discussions. Valuable comments and recommendations from reviewers of early versions, including L. Oliver, S. Jordan, R. Anderson, G. Roesijadi, and M. Carriker are greatly appreciated. This was prepared in support of the Gulf Ecology Division mission in Altered Habitat, and is GED contribution #1196.

RELATIONSHIP OF AMEBOCYTES AND TERRESTRIAL ELEMENTS TO ADULT SHELL DEPOSITION IN EASTERN OYSTERS

WILLIAM S. FISHER

United States Environmental Protection Agency, Office of Research and Development, National Health and Environmental Effects Research Laboratory, Gulf Ecology Division, 1 Sabine Island Drive, Gulf Breeze, FL 32561

ABSTRACT Freshwater runoff contains terrestrial elements from geologic deposits that may be vital to survival of eastern oysters *Crassostrea virginica*, a factor that could account for their distribution near terrestrial watersheds. Some of these elements are accumulated in granules of oyster amoebocytes, which are highly mobile, diapedetic cells with widely-recognized roles in oyster defense and nutrition. Amoebocytes are known to discharge antimicrobial substances from membrane-lined cytoplasmic granules into extracellular spaces, a process referred to as degranulation. A similar, if not identical, process has been described for discharge of copper and zinc from cytoplasmic granules to precipitate hemolymph proteins and initiate clotting. This review examines evidence that supports amoebocyte involvement in eastern oyster shell deposition and a potential role for accumulated terrestrial elements in crystallization. It is proposed that metal-bearing amoebocytes discharge inorganic elements that precipitate proteins and initiate or facilitate shell crystallization. Support for this conjecture derives partly from high concentrations of terrestrial elements in adult shell, changes in shell morphology at metamorphosis, hypothesized mechanisms for shell repair and pearl formation, and the absence of other known mechanisms for shell crystallization.

KEY WORDS: oysters, *Crassostrea virginica*, marine bivalves, copper, metals, contaminants, amoebocytes, leucocytes, hemocytes, larval setting, larval metamorphosis, shell deposition, metal toxicity, oyster management, oyster reef restoration

INTRODUCTION

Population distributions of eastern oysters *Crassostrea virginica* near terrestrial watersheds has led to a general impression that low or variable salinity is vital to their survival (Coke 1983, Soniat & Brody 1988, Berrigan et al. 1991). However, freshwater runoff contains numerous mineral elements from geologic deposits that could perform significant functions in oyster physiology. Copper and zinc, for example, are accumulated to extraordinarily high concentrations in eastern oysters, even in the absence of anthropogenic sources. There is no known physiologic function for such high concentrations of these terrestrial metals, but it has been proposed that they are actively assimilated and stored in amoebocyte granules for antimicrobial activities related to defense and nutrition (Fisher 2004). Both metals are accumulated in the amoebocytes and calcareous shell of oysters, a unique distribution that indicates a link between amoebocytes and deposited shell, the initial and final repositories for the metals.

Because amoebocytes (blood cells, hemocytes) are known to recognize, locate, ingest, and digest a variety of biotic and abiotic foreign particles (phagocytosis), the role of amoebocytes in microbial defense has been widely investigated (Metchnikoff 1891, Yonge 1926, 1937, 1946, Stauber 1961, Cheng 1975, 1977, 1996, Feng et al. 1977, Feng 1988). A hypothesis that copper and zinc are instrumental in amoebocyte antimicrobial activities was generated from evidence that the metals are avidly concentrated by eastern oysters from low ambient concentrations, and are retained in amoebocyte granules for relatively long periods of time despite available elimination mechanisms (Fisher 2004). There is evidence that copper and zinc, stored at high concentrations in amoebocyte granules, can be discharged into phagosomes for intracellular killing or into extracellular spaces (degranulation) at wound sites for microbicidal action and clot formation (Ruddell 1971, Sparks 1972, Brown 1975, Ruddell & Rains 1975). Here, discharge of

metals is proposed as a mechanism to initiate or facilitate shell crystallization.

The importance of the oyster shell is indisputable; shell structure, strength, and growth are critical factors in oyster survival. According to Melbourne R. Carriker, an authority on eastern oyster shells and shell formation,

"Because the oyster lacks an internal skeleton, its valves serve as an exoskeleton, providing support for the soft internal organs and preventing collapse of the mantle cavity. Consequently, vital physiologic functions of the mantle cavity, i.e., circulation of seawater, gaseous exchange, discharge of gametes, and removal of pseudofeces and fecal and catabolic wastes, can be carried out without impediment. Valves also protect internal organs from mechanical impacts, osmotic stress, and many predators, and from desiccation in the intertidal zone." (Carriker 1996, p. 102).

The greatest attributes of shell, its strength, and stability, are obtained through crystallization, which binds disassociated elements into an inflexible crystalline lattice as the shell is deposited. In this overview, evidence is presented to link shell deposition with activities of amoebocytes and with the discharge of metals from amoebocyte granules that may serve to initiate or facilitate crystallization. As crystallization proceeds, the metals are irreversibly bound and accrue to high concentrations in the shell. Amoebocyte involvement in shell deposition is supported by the existence of high concentrations of terrestrial metals in deposited shell, differences in larval and adult shell structure, and the potential role of metal deposition in shell crystallization. Like defense and nutrition, deposition of shell serves an important survival function for oysters, meriting the expenditure of energy necessary to accumulate and deposit the metals. A dependence of oysters on terrestrial metals could account for their exclusively estuarine and near-coastal distribution.

AMEBOCYTE INVOLVEMENT IN SHELL DEPOSITION

The chemist M. E. Fremy found that molluscan shell was composed primarily of carbonate of lime which, when treated with hydrochloric acid, left a

"... brilliant, felt-like residue, not soluble in hot water, like horn or gelatin, and insoluble in alcohol and ether."
(Woodward 1866)

Fremy named the organic substance *conchioline* and, because it retained its structural integrity after acid treatment, demonstrated that the shell was not a single network, but two distinct components. Fremy's discovery led to the hypothesis that an organic framework of conchioline (or conchiolin, Fig. 1) was formed from cells or layers of membrane (Bowerbank 1844, Carpenter 1844, Woodward 1866), and lime was then deposited upon this framework. The concept of a two-step process has endured (Crenshaw 1980, 1982, Wilbur & Saleuddin 1983), as summarized by Carriker (1996).

"Shell formation occurs in two major steps: (a) ion transport, protein synthesis, and secretion by mantle epithelial cells, and (b) physicochemical processes in the extrapallial space in which mineral crystals are nucleated, oriented, and grow in intimate associate with the secreted organic matrix." (Carriker 1996, p. 123)

Mantle tissue has long been considered the organ responsible for both steps of shell deposition.

Figure 1. Conchiolin matrix of *Crassostrea virginica*. Acid treatment or standing sea water removes the mineral core (c) of shells to reveal the sheaths (s) of organic matrix that are insoluble and acid-resistant. Figures from Carriker (1996, Figs. 99 and 100), courtesy of Maryland Sea Grant and with permission of the author.

"The growth of shell results from the deposition of crystalline material within an organic matrix of conchiolin by a thin sheet of tissue called the mantle, which lines the inner surface of the shell." (Tsuji et al. 1958, p. 276)

"Biocrystals develop in the extrapallial space within the soluble matrix (between the inner shell surface and the outer mantle epithelium) from mineral and organic material passed through or originating in the mantle epithelium." (Carriker 1996, p. 122)

This widely held perception is drawn from the close association of mantle tissue with new shell surfaces and the highly secretory nature of mantle epithelium. Yet, amoebocytes, often high in number, are also present in the extrapallial spaces of bivalves (Wagge 1955, Beedham 1965, Bayne 1983) including eastern oysters (Pailard et al. 1996). And, whereas the mantle is considered the primary tissue for shell deposition, amoebocyte participation has often been implicated. Based primarily on the suggestions of Wagge (1955), several reviews of bivalve amoebocytes have concluded that amoebocytes participate in shell repair (e.g., Narain 1973, Cheng 1981, 1984, Fisher 1986). Despite this connection, there has been, until recently, no direct evidence of amoebocyte involvement in shell repair or shell deposition in eastern oysters.

Early Observations

There is fortuitous evidence that bivalve amoebocytes participate in shell deposition. Although Woodward (1866) conformed to the hypothesis that mantle tissues were responsible for shell, he inadvertently described something that might be interpreted differently:

"If we examine any immature shell, we shall find the lip, or growing margin of the shell, much thinner than the rest of the shell, and, indeed, quite soft. The mucus of this soft, growing edge is found to contain granules, which are, in fact, incipient cells destined to unite and form the calcareous matter of the future shell-wall." (Woodward 1866, p. 250)

It is not clear from this description how 'incipient cells' might fuse into shell material, but there can be little doubt that Woodward observed granular cells in the mucus of the growing shell edge that he believed were responsible for shell calcification. He anticipated that these cells were derived from mantle epithelium, but his characterization could also describe migrating amoebocytes.

In another example, Bevelander and Martin (1949) described the *in vitro* culture of excised mantle tissue from *Pinctada radiata*. They reported that strips of mantle could secrete mucus, epithelial cells, blood cells, and fibrous material (conchiolin) which formed shell-like material.

"Cultures maintained for longer periods, 4-6 days, frequently exhibit the presence of crystal aggregates typical of those found in normal or regenerating shell. In the majority of these preparations the crystal formation occurs some distance away from the mantle edge, and usually in an exudate consisting of mucus." (Bevelander & Martin 1949, p. 614)

This short abstract (Bevelander & Martin 1949) is significant because it demonstrates, at least for *P. radiata*, that both conchiolin formation and crystallization can occur without direct contact with mantle epithelial cells. Instead, the abstract noted blood cells (amoebocytes) in the mucus where new shell was being formed.

Shell Repair In Land Snails

One of the most compelling arguments for amoebocyte participation in shell formation stems from the insights of Wagge (1951, 1955), who studied shell repair and deposition in the land snail *Helix aspersa*. Wagge (1955) found that during new shell deposition, calcium carbonate was passed from mantle epithelial cells into the extrapallial cavity to form a colloidal gel that crystallized into shell. But he questioned how mantle cells could perform repairs throughout the entire shell.

"To what extent do the mantle epithelial cells act in situ when they are laying down new layers of shell, or absorbing calcium from other parts of the shell? They could not lie in positions in which they were found in certain regenerates and at the same time have remained an integral part of the mantle epithelium." (Wagge 1955, p. 45)

His principal concern was that stationary mantle epithelial cells could not reach remote or restricted sites. He also questioned how these cells could absorb material (e.g., calcium) from one site and transport it to a different site for shell deposition. Finally, he wondered how secretions that emanated grossly from mantle tissue could avoid forming new shell throughout the mantle cavity, even if repairs were needed at only a single site. All of these issues were resolved by his observation of mantle epithelial cells that were capable of amoeboid activity.

"The foregoing account has shown that mantle epithelial and connective tissue cells are able to: (1) absorb calcium, (2) move it to a damage area, (3) secrete the organic and crystalline framework of the new piece of shell. With freely moving cells the physico-chemical reaction can take place directly within the restricted area under repair, and not generally throughout the whole of the extrapallial fluid." (Wagge 1955, p. 48)

The presence of amoeboid cells alleviated Wagge's concerns over proposed mechanisms of shell repair, and led him to wonder whether similar mechanisms were also used in formation of new shell.

"This fact, i.e. that certain mantle cells are capable of independent movement, helps considerably in the understanding of the part played by the mantle during shell formation, although whether there is as much independent movement of cells from the mantle during the formation of new shell, as there is during repair, is not known." (Wagge 1955, p. 44)

Many of Wagge's conclusions were formed by his earlier experiments (Wagge 1951) that showed migrating epithelial cells were responsible for secretion of both the organic membranes and the crystals of calcium carbonate within the calcospherites (conchiolin compartments). Although these observations were made on *Helix*, they formed the basis of later assertions that amoebocytes are involved in molluscan shell repair (e.g., Narain 1973, Cheng 1981, 1984, Fisher 1986). They also provide a rationale and a model for amoebocyte involvement in new shell deposition.

Pearl Formation and Deposition of Nacre

Wagge was not the first to recognize amoebocyte participation in shell deposition. Early bivalve studies established that pearls were composed of material identical to, and formed in the same manner, as the nacreous inner lining of their shells. Louis Boutan (1923) attributed to Raphael Dubois (1901) the first true investigation into the process of pearl formation. The essence of Dubois' work on

Mytilus edulis was recalled in Boutan's extensive overview of natural and cultured pearls:

"La nacre, dit-il, n'est pas, comme on l'a répété jusqu'à ce jour, le produit d'une sécrétion glandulaire. Son mécanisme de formation est plus complexe. L'épithélium externe du manteau des Mollusques naçriers sécrète le squelette organique de conchyoline. Les interstices de ce dernier sont comblés par des éléments migrateurs calcarifières, qui traversent l'épithélium sécréteur par un phénomène de diapédèse. La substance inorganique (carbonate de chaux) des éléments migrateurs est nécessairement mélangée à une certaine quantité de matière organique ayant constitué la substance vivante ou bioprotéine du plastron calcarifière." (Boutan 1923, p. 23)

Boutan (1923) emphasized that the importance of Dubois' work was his description of a two-step process in pearl formation: an organic layer deposited by the mantle epithelium and the limestone calcification provided by migratory cells. Pearls, according to Dubois, were formed by "*un charpentier et un maçon*". Boutan (1923) was not certain whether the migrating cells originated as ectoderm (from the basement membrane of mantle epithelial cells) or were mesodermal cells that migrated across the mantle epithelium (Fig. 2). Regardless, he seemed quite certain that amoeboid cells played an essential role in the crystallization of both shell nacre and pearls, the former stimulated by normal growth processes and the latter by the abnormal presence of a foreign object.

"En résumé, la structure de la perle et de la nacre paraît dépendre uniquement du concours de deux éléments dis-

Figure 2. Drawings to show (1) a section of the epithelium forming a pearl sac, including the epithelial cells *ep*, basement membrane *b*, mesoderm *m*, and amoebocytes *a*; (2) the basement membrane of the epithelium as a potential site of origin for amoebocytes; and (3) the mesoderm as a potential site of origin for amoebocytes, and their migration to the surface of the epithelial layer to calcify the pearl. Drawings are by A. Rubbel, reproduced from Boutan (1923, Fig. 1).

ments, fournis, l'un par l'épithélium, l'autre par un élément cellulaire, dont l'origine reste incertaine. On comprend facilement que cette structure puisse être influencée par l'état de l'épithélium normal dans le cas de la sécrétion de la nacre, anormal dans le cas de la formation de la perle fine, aux dépens d'un sac clos dérivé de la épithélium." (Boutan 1923, pp. 24-25)

He showed that the cells forming the pearl sac were extensions of the mantle epithelium (see Fig. 2) that appeared to be in a state of chronic inflammation (Boutan 1923, p. 22). The findings of Dubois and Boutan were no doubt instrumental in Wagge's (1955) conclusion that migrating ameboid cells were essential contributors to shell formation.

Recent evidence has emerged that directly links amebocytes to deposition of shell (Mount et al. 2004). Scanning electron microscopy and x-ray microanalysis were used to document the formation in certain granular amebocytes (refractory cells) of calcium carbonate crystals that were then deposited at the site of shell repair. There is no evidence yet of how the crystals are formed or whether all granulocytes have the capacity to form them. Crystals were observed in amebocyte cytoplasm and later distributed at the shell mineralization front. This may be the first direct evidence for eastern oyster amebocyte involvement in shell deposition.

ACCUMULATIONS OF METAL IN EASTERN OYSTER SHELL

Eastern oyster shells contain high concentrations of terrestrial metals. There have been many reports of high metal content in eastern oyster soft tissues (see Fisher 2004), but shells also accumulate high amounts. For example,

"Soft parts of oysters showed on the average about six times the zinc concentration of the shells (wet weight basis). But since the soft parts accounted for only $19.5 \pm 4.1\%$ of the total live weight of the oysters, however, the shells contained nearly 45% of the total zinc in this group of oysters." (Wolfe 1970, p. 52)

Although values reported for oysters vary (Table 1), metal concentrations are consistently found to be higher in shells than in the surrounding seawater. Ferrell et al. (1973) estimated that many metals (Pb, Hg, Cd, Zn, Cu, and Cr) in *C. virginica* shells were more than a thousand times higher than seawater concentrations.

TABLE 1.

Concentrations of metals in eastern oyster shell reported by different sources.

Metal	Concentration ($\mu\text{g g}^{-1}$)	Source
Aluminum	200	Smith & Wright 1962
Cadmium	8-10	Ferrel et al. 1973
Chromium	2-4	Ferrel et al. 1973
Copper	3	Smith & Weight 1962
	43-70	Ferrel et al. 1973
Iron	180	Smith & Wright 1962
Lead	36-41	Ferrel et al. 1973
Manganese	110	Smith & Wright 1962
Mercury	0.09	Ferrel et al. 1973
Zinc	2	Smith & Wright 1962
	25	Wolfe 1970
	2-8	Windom & Smith 1972
	5-9	Ferrel et al. 1973

"The trace metals are present in substantially higher concentrations than in sea water, thus illustrating the degree of accumulation possible during the secretion of the shell by the mantle of the oyster." (Ferrell et al. 1973, p. 315)

This assessment has been upheld by others (Carriker et al. 1980, 1982, 1991, Simkiss 1983).

Metals Acquired During Shell Deposition

There is an apparent consensus, evident from the earlier citation, that incorporation of metals in oyster shell occurs as the shell is deposited. The consensus, at least for zinc, seems to be correct. Wolfe (1970) found little difference in zinc concentrations of living oyster shell with that of geological deposits of oyster shell.

"Zinc may be released from the shell matrix very slowly, so that shells represent a significantly large reservoir of zinc with a slow turnover in the environment." (Wolfe 1970, p. 52-53).

Slow release from shell implies that zinc is tightly bound in the shell matrix and is not in rapid flux with ambient concentrations. This means that zinc is incorporated during shell deposition, when it can be tightly bound in the crystalline matrix.

There is, though, some flux of zinc between existing shell and the environment. Studies have shown a rapid uptake and exchange between ^{65}Zn in shell and in the water column (Chipman et al. 1958, Fitzgerald & Skauen 1963, Wolfe 1970, Romeril 1971), seemingly due to adsorption and release driven by ambient concentrations. Chipman et al. (1958) noted that addition of ^{65}Zn adsorbed to shells initially, but if oysters were moved to untreated water the isotope disassociated from the shells to establish a new steady state with the surrounding water. Although these studies demonstrate the ability of zinc to adsorb to shell, adsorbed amounts are probably minor in relation to those amounts bound in the shell matrix.

There are two general mechanisms that could bind metals during shell deposition: (1) metals could be incorporated directly from the ambient environment over time, or (2) metals could be incorporated as needed from internal stores. The first possibility presumes that oyster shells grow sufficiently slow to concentrate metals available in the ambient milieu. Even though ambient concentrations are usually low and often variable, many elements form carbonates that could be directly incorporated (Ferrell et al. 1973). Certainly, this is possible if, as some have argued, shell accumulation of trace metals is,

"... partly a coincidental result of poor discrimination by the biologic mechanism for calcium uptake and shell deposition." (Wolfe 1970, p. 55)

But a similar argument for high concentrations of copper and zinc in oyster soft tissues was found lacking. Rather than inadvertent uptake, accumulation of copper and zinc is more likely a dedicated physiologic process to acquire the metals for nutritional and defense activities of amebocytes (Fisher 2004).

Metals Provided by Amebocytes

The second possibility for metal incorporation in shell presumes that some mechanism is available to concentrate metals, store them safely (i.e., without toxic effect), and discharge them into the organic matrix as shell is deposited. Amebocyte storage of metals fulfills each of these conditions. Copper and zinc are sequestered in membrane-lined granules of amebocytes to prevent

toxicity, then discharged into extracellular spaces as needed for antimicrobial activity (Ruddell 1971). Although existing data are largely limited to copper and zinc, it is very likely that other metals found in shell, such as iron, manganese, and tin, are also stored by amebocytes (Orton 1923, Galtsoff 1938, 1953, 1964). If so, then amebocytes may be an internal storehouse for a variety of metals ultimately incorporated into shell. This second alternative is reinforced if the metals are incorporated to serve some function in shell deposition, architecture or integrity. As such, their availability would become a limiting factor in shell growth and necessitate a stable and readily available source of metals, especially at times of rapid growth. This alternative would present a distinct advantage over accrual from the low and variable amounts provided by ambient waters.

Higher Metal Concentrations in Adult Shells

It has been demonstrated that adult shells of eastern oysters have higher concentrations of metals than larval shells. Carriker et al. (1991), using proton-induced x-ray emission data showed that metal content in calcite (adult) shell, particularly prismatic forms, was higher than in aragonite (larval) shell. Although the studies were performed entirely on adult oysters, the section of shell containing the myostracal scar retains the aragonitic shell structure of larvae. These data confirmed earlier results (atomic absorption spectrophotometry, Carriker et al. 1980) that compared prismatic calcite shells with the foliated structure of the internal shell surface. Although the contents varied, the prismatic calcite shells contained more zinc, iron, and other metals than the myostracal and foliated shell types (Table 2). These studies link higher metal content to calcite shell morphology, the form of shell that is produced by juveniles and adults after larval metamorphosis.

METAMORPHIC CHANGES IN AMEBOCYTES AND SHELL STRUCTURE

The foregoing sections have described observations of amebocyte involvement in shell deposition and the high accumulation of metals bound in the shell matrix. Because at least some of these metals are avidly assimilated and concentrated in amebocytes, which have mechanisms for safe storage and discharge, it is hypothesized that amebocytes deposit the metals into newly forming shell. Adult eastern oyster shells have higher concentrations of metal than larval shells so, if there is an association among amebocytes, metals, and shell structure, then there must be a funda-

TABLE 2.

Mean distribution of elements in different eastern oyster adult shell types, analyzed by proton-induced X-ray emission and reported as % by elemental weight in ppt (from Carriker et al. 1991, Table 3). These selected, but representative results demonstrate greater metal content in prismatic shell than foliated and myostracal scar shell. Myostracal scar shell is considered representative of larval aragonite shell structure. Carriker et al. (1991) report similar data on several valve types and shell sections, and examine 15 elements, including Na, Mg, S, Cl, Ti, Cr, Br and Sr not shown here.

Shell Type	Al	Si	Ca	Mn	Fe	Cu	Zn
Prismatic	11.09	21.21	908	0.543	4.782	0.024	0.122
Foliated	<0.50	<0.50	961	0.153	0.601	<0.010	0.088
Myostracal	1.55	<0.50	975	0.012	0.042	<0.010	0.012

mental difference in how shell is deposited before and after metamorphosis.

Structural Differences Between Larval and Adult Shells

A relatively unique difference exists between adult and larval shells of eastern oysters; the larval (prodissoconch) shell is aragonite (highly regular arrangement) and the adult shell is calcite (irregular, prismatic arrangement). Transition from one shell form to the other occurs simultaneously with larval setting and metamorphosis. Stafford (1913) described the visible distinction between the prodissoconch shell, which remains the same size once the oyster has set, and the juvenile/adult shell that grows from the margin of the larval shell (Fig. 3). The structural demarcation of the two shell types is termed the *metamorphic line* (Carriker 1996).

Figure 3. Growth of the shell of *Crassostrea virginica* from the time of settlement through early spat growth. The metamorphic line delineates a transition from the aragonite shell of larvae, shown in (1) with a thin rim of newly deposited spat shell, to the calcite shell of juveniles and adults. Sizes of spat in the drawings range from 0.379 mm (1) to 2.25 mm (7) in length. The largest spat drawn (7) is eight larval shells superimposed so that the shells coincide to represent a spat at different stages in its growth from 0.5–2.25 mm length. Reproduced from Stafford (1913; Plate II).

Beyond the metamorphic line, shell structure is prismatic calcite on external portions (Fig. 4) and foliated calcite on internal portions. The reason for the structural change at metamorphosis is not understood, although Stenzel (1964) believed it to be because,

"... calcite is more stable and much less subject to leaching in the sea water and because calcite can be secreted more economically than aragonite. Secreted calcite fills a larger volume per mole than aragonite. Adult oysters need a thick shell for defense against predators." (Stenzel 1964, p. 156)

Wise (1970) suggested that substitution of calcite shells in place of aragonite shells represented an evolutionary change driven by expediency. Apparently, animals secreting calcitostracum can simultaneously form multiple laminae in the organic matrix, thereby speeding the process of shell crystallization.

Regardless of evolutionary purpose, this change at metamorphosis must accompany a fundamental modification in the manner that shell is deposited. Carriker (1996) marveled at the probable physiologic alterations this would entail.

"Change in shell microstructure and mineralogy during metamorphosis probably could not occur without some

modification of the secretion of the shell materials by the mantle epithelium. Epithelial cells, which in planktonic larval stages secreted aragonitic granules, quite suddenly are reconstituted in the early spat to form a microstructure and orientation of strikingly different biocrystals at the rim of the valves." (Carriker 1996, p. 97)

Yet, evidence is lacking that indicates any modification of the mantle epithelium:

"Of lively interest is the subtle cellular differentiation that must occur in mantle margins at metamorphosis. Are microstructural and microchemical changes evident at the cellular and molecular level by modern scientific technology? Unfortunately, knowledge of these metamorphic changes is essentially nonexistent." (Carriker 1996, p. 157)

A reason for this lack of knowledge may be that the transformation of shell structure has little to do with cellular differentiation in the mantle. Instead, the transformation may be driven by changes in the activities of amoebocytes.

Relation of Copper to Larval Metamorphosis

A review of functional roles for terrestrial metals in eastern oysters could not be complete without considering the research of Herbert F. Prytherch, Director of the US Fisheries Biological Station in Beaufort, North Carolina. During the late 1920s, Prytherch performed studies at Milford, Connecticut, to describe the process and events of oyster setting and metamorphosis. Like many others, Prytherch (1929, 1934) noted that eastern oysters were invariably distributed along inshore areas and near the mouths of rivers, locations that exhibited a continuous mixing of seawater and river water. Heaviest oyster setting occurred during neap tides when river flow and lower salinities dominated, and could extend seaward during periods of high river discharge. His laboratory experiments demonstrated that salinity had little influence on setting success, although it did affect the time required (Fig. 5). More important to successful setting, he found, were the components of river water.

"When the salinity was reduced with river water instead of distilled water, the larvae gave a positive setting reaction which indicated that some change or substance had been introduced by the river water that served to stimulate and induce setting." (Prytherch 1934, p. 68)

He later found that substance to be copper, which induced setting "almost immediately" (15–30 sec) when a 0.5 cm square piece was dipped into sea water.

Prytherch (1934) attempted to find other conditions and chemicals that might induce larval setting. He found no effect of temperature, salinity, pH, oxygen content, carbon dioxide content, water pressure, or current velocity. Neither neutral salts (chlorides, sulphates, carbonates, and nitrates of sodium, potassium, magnesium, and calcium) nor inorganic elements (Ag, Al, Ba, Fe, Mn, Ni, Pb, Sn, and Zn), other than copper, had any effect (Table 3).

"The only element in the heavy metal series that produced a positive setting reaction was copper in the form of a pure metal or as a dissolved salt. This heavy metal was found to be effective and initiated almost immediately the setting process in concentrations as low as 1 part copper to 25 million or 50 million parts of sea water. In the controls the larvae lived for a week or two but eventually died after failing to set or metamorphose. However, if copper stimulation was applied during this period the larvae would set and develop into healthy spat." (Prytherch 1934, p. 77)

Figure 4. *Top:* Settled spat of *Crassostrea virginica* showing the metamorphic line (arrow) that distinguishes shell generated during the larval (prodissoconch, p) stages from that generated after oyster setting (dissoconch, d). *Bottom:* Metamorphic boundary (arrow) showing differences in shell structure. From Carriker (1996, Figs. 40 and 41), courtesy of Maryland Sea Grant and with permission of the author.

Figure 5. Effect of salinity on duration of eastern oyster setting (Prytherch 1934). Late-stage oyster larvae were acclimated 1-3 days at salinities ranging from about 4-40 ppt prepared from stock sea water (28 ppt salinity) by evaporation or dilution with distilled water. Larvae were induced to settle with addition of very small amounts of copper, and the time required to set was monitored. No setting occurred after 4 h for larvae maintained in salinities below 5.6 ppt or above 32.2 ppt. Data are representative of over 450 larvae tested in this manner. Redrawn from Prytherch (1934, Fig. 9).

He later refined his estimate of the required copper concentration to range from 50 to 600 $\mu\text{g L}^{-1}$, and demonstrated greater setting success at the high end of the range.

Relation of Copper and Pigment Spots to Metamorphosis

Once an eastern oyster larva has set, numerous morphologic changes occur, including disappearance of the pigment spots, atrophy of the velum and foot, rapid growth of the gills and mantle, development of the adductor muscle, and an increase in heart rate. Among these transformations is the appearance of circulating amoebocytes in the hemolymph. The amoebocytes originate, according to Prytherch (1934), from the pigment spots, blue-green aggregates of cells (Fig. 6) that disappear at metamorphosis.

"When setting is in progress, the pigmented cells in each spot gradually enlarge, separate, and one or two break away and are carried forward by the blood stream into the mantle. After [larval] attachment, the pigment spot breaks apart more rapidly; and all the cells become distributed in a short time into the circulatory system, as the process of transformation of the larva is in full swing. Each pigment spot consists of approximately 300 cells which, after sepa-

TABLE 3.

Metals tested by Prytherch (1934) for ability to induce setting in eastern oyster larvae. Each concentration of each element was tested at 15, 20, and 25 ppt salinity at both pH 7.5 and pH 8.0.

Element	Form	Concentration Range ($\mu\text{g L}^{-1}$)	Larval Setting	
Aluminum	$\text{Al}_2(\text{SO}_4)_3$	1-20	Negative	
	AlCl_3	1-20	Negative	
	Metallic	1 min-6 hrs ^d	Negative

	Metallic	1 min-6 hrs ^d	Negative	

^a Metallic forms were immersed in the sea water for the durations noted.

^b Copper concentrations above 500 $\mu\text{g L}^{-1}$ were toxic to larvae; lower concentrations of all copper salts stimulated setting.

ration, resemble in many respects the leucocytes of the spat and adult oyster. The breaking up of the pigment spots is an important and necessary preliminary step to metamorphosis, and requires copper as the initial stimulus." (Prytherch 1934, p. 86)

Prytherch demonstrated that pigment spot dispersal and metamorphosis ceased if copper were removed from the medium, even for newly set organisms.

The pigment spots have often been called "eyespot" and, because they appear only near the end of larval maturation, their presence has been used to signal mature larvae that are ready for setting ("eyed" larvae). Although the source has not been investigated, the increasing visibility of pigment spots with larval devel-

Figure 6. Left side of a *C. virginica* larva showing the pigment spot (P.S.) connected by a vessel to the heart (H.). At metamorphosis, Prytherch (1934) has observed the approximately 300 cells that comprise each pigment spot to disperse into the blood vessels and become the circulating amebocytes of spat. The pigment spots have also been termed 'eye spots', although evidence of sensory capacity is lacking. Other organs include shell (Sh.), intestine (I.), stomach (St.), byssal gland (Bg.), liver (L.), posterior adductor muscle (A.m.), gills (G.), mantle (M.), byssal secretion (B.S.), anus (A.), velum (V.), mouth (Mo.) and foot (F.) Drawing reproduced from Prytherch (1934, Fig. 4) with permission of *Ecological Monographs*.

opment is probably due to increasing concentrations of accumulated copper. As copper is accumulated, the amebocytes gradually become more visible—just as they become visible on mantle surfaces, hearts, and blood vessels when carrying high concentrations of copper (see Fisher 2004). Prytherch (1934) recognized this likely association:

"Metamorphosis follows the release into the circulatory system of the numerous cells, containing a blue-green pigment, which compose each pigment spot. According to Galtsoff and Whipple (1930) there is a definite relation between the green pigment in adult oysters and the amount of copper present. These authors found that the intensity in green color was in proportion to the copper content of the oyster and that histologically the copper is located in the green leukocytes." (Prytherch 1934, p. 87)

For Prytherch, the significance of copper as an integral part of metamorphosis was based on his belief that copper was essential for respiration. He postulated that copper porphyrin served as a respiratory catalyst similar to iron porphyrin in vertebrates. This link with respiration provided Prytherch a rationale for the unique copper requirement he had discovered, and led him to view the release of the pigment spot cells into the blood stream as a key event in the life of the oyster.

"Though many morphologic changes occur in the transformation of the larva into an adult oyster, those which appear to be of greatest biologic significance are concerned with the breaking up of the two pigment spots after ingestion of minute amounts of copper." (Prytherch 1934, p. 87)

Although respiratory pigments have not been found in eastern oysters, the association of copper with setting and metamorphosis

is highly intriguing. Yet, it has received little attention in subsequent literature.

The link between pigment spot amebocytes and metamorphosis was disputed by Cole (1938) who believed *O. edulis* pigment spots were sensory eye spots. This he apparently concluded from their bilateral symmetry and histologic characteristics, because there were no descriptions of neural connections (Stafford 1913, Prytherch 1934, Cole 1938). He believed that larvae developed sensitivity to light to ensure setting in dark, protected locations, a hypothesis that is still unresolved (see Kennedy 1996). Instead of dispersal, Cole (1938) believed that the "eyespot" cells disappeared at metamorphosis because they were phagocytosed by amebocytes. Cole's position was adopted by Galtsoff (1964) for *C. virginica* and, except for one passing note (Vinogradov 1953), the possibility that pigment spots are immobile amebocytes has apparently been abandoned.

Nonetheless, there is indirect evidence that copper influences the activation and activity of oyster amebocytes. Field studies have shown that oysters with high tissue concentrations of copper had higher numbers of locomotory amebocytes and higher rates of amebocyte locomotion (Fisher et al. 2000, Oliver et al. 2001). Also, aggregation and dispersal of oyster amebocytes can be controlled *in vitro* by the presence or absence of cations in the medium (Fisher & Newell 1986). Without cations in the seawater, amebocytes drawn from oyster hemolymph remained immobile and aggregated. Dispersion did not occur until cations were reintroduced. This observation is similar to that of Prytherch (1934), who found mobility and dispersal of pigment spot amebocytes was dependent on the presence of copper.

TERRESTRIAL ELEMENTS AND SHELL CRYSTALLIZATION

Bevelander & Nakahara (1969) substantiated an early hypothesis that the organic matrix (conchiolin) of marine bivalves was elaborated across the growth surface of new shell in advance of mineralization. The matrix formed compartments that contained substances necessary for crystallization. In pelecypods, crystal initiation is believed to occur randomly at "nucleation sites" within the matrix compartments (Wise 1970). Once initiated, crystals grow and coalesce to form the larger crystals and shell patterns observed microscopically (Tsujii et al. 1958, Wise 1970, Carrier 1996).

"It is thought that formation of an organic matrix probably precedes formation of biocrystals. The matrix in all likelihood is involved in the nucleation, orientation, type, and size of biocrystals, and in providing the surface to which soluble matrix attaches and functions as a nucleating surface. It has been suggested that once crystal nuclei are formed, biocrystals grow inorganically." (Carrier 1996, p. 122)

Evident throughout the literature, however, is a lack of detail related to mechanisms of nucleation and crystal initiation. Galtsoff (1964) related hypotheses of nucleation by carbon dioxide (De Waele 1929) and citrate (Steinhardt 1946), but was not convinced that either was true. Later, Towe and Hamilton (1968) suggested that the organic matrix became polymerized into layered sheets that provided nucleation sites for epitaxial precipitation of calcium carbonate. This is probably a reasonable reflection of the proposal of Bevelander and Nakahara (1969), who suggested that the organic matrix provided a "proper environment" for spontaneous crystallization.

Yet, it became clear that if spontaneous precipitation led to

crystal growth, then there must be some means to halt the process and confine mineralization within the conchiolin compartments. Microstructure analysis has indicated that crystallization occurs independently within each compartment (Wise 1970). A possible resolution was suggested by Tsujii et al. (1958):

"It is apparent that some mechanism exists for maintaining the height of the matrix and the crystal surface at approximately the same level. Movements of the mantle probably accomplish this by distributing secreted matrix. If the crystal faces become higher than the matrix boundaries through crystal growth, the mantle movements would fill in the depressions between crystals with matrix. Excess material would be moved across the crystal faces." (Tsujii et al. 1958, p. 277)

This explanation, however, seemed to imply a second secretion of matrix from the mantle, somehow guided by muscular movements of the mantle to specific sites exhibiting excess crystal growth. Carriker (1996), apparently recognizing the inherent conflict of a matrix material that both initiated and limited crystal growth, attempted to refine the concept.

"As a stratum (lamina) of biocrystals attains a certain thickness, apparently a layer of insoluble matrix is added and then sclerotized in situ, stopping further thickening of the layer. As a consequence, the inner surface of valve thickens incrementally. The mechanism for this stratification, involving mantle secretory cells and the complex of secretions in the extrapallial space, is unknown." (Carriker 1996, p. 122)

As implied, Carriker found no evidence for deposition of a second layer of matrix or its sclerotization.

The issue described here is not confined to eastern oysters. In most shell-forming organisms it is generally believed that the organic matrix is somehow responsible for regulation of crystallization (Crenshaw 1980, Mann 1983, Weiner et al. 1983), whether through initiation or limitation of crystal growth, or influence over crystal type and shape (Wheeler et al. 1988). Many apparently believed that the matrix was involved in crystal initiation (Wheeler & Sikes 1984), so it was unexpected when Wheeler et al. (1981) found organic matrix, resolubilized from shells of *C. virginica*, actually inhibited *in vitro* crystallization. This evidence led Wheeler et al. (1987) to question the applicability of *in vitro* indicators and to suggest an alternative to the existing "calcium binding" concept for crystal nucleation. They proposed instead "crystal binding", in which soluble matrix actually binds to and stabilizes clusters of ions "which form and dissolve repeatedly in metastable physiologic solutions" (p. 958-959). Despite these efforts, it seems that the role of matrix in calcification remains an enigma.

Overlooked in these investigations was the fact that amoebocytes carrying high concentrations of accumulated copper, zinc, and probably other cationic metals traverse the surface of the conchiolin matrix. This fact affords an alternative mechanism: Amoebocytes on the matrix surface could discharge stored metals onto the matrix to precipitate proteins (or even salts) and initiate crystallization. A mechanism for such a process was previously proposed by Brown (1975) for initiation of clotting in eastern oyster hemolymph. Brown suggested that metals discharged from amoebocytes (degranulation) precipitated proteins in the hemolymph plasma to create a finely granular gel, or clot, capable of trapping bacteria. Metal-laden amoebocytes in mucus of the mantle cavity may similarly mobilize to sites of shell deposition (whether for

repair or new growth) and discharge stored metals that precipitate proteins for the formation of crystals.

Such a mechanism would explain two phenomena, crystallization and the transfer of metals from amoebocytes to shell. Recent research, however, has demonstrated that crystals are formed within granular amoebocytes and then released onto the surface of the matrix (Mount et al. 2004). It is conceivable that metal-protein precipitation is responsible for the formation of crystals within the amoebocyte. Alternatively, metals could be dispersed by degranulation onto the conchiolin surface after the release of crystals to facilitate crystal growth or alter the crystal structure for strength or efficiency (i.e. formation of calcite rather than aragonite). Certainly, these new findings indicate that nucleation may not be so simple as metal-protein precipitation on the conchiolin surface. Nonetheless, it is very probable that granular amoebocytes at the site of shell growth are simultaneously involved in both shell deposition and the transfer of metals to shell.

Proposed Role of Amoebocytes and Terrestrial Elements in Shell Crystallization

Based on the earlier information, a role for amoebocytes and terrestrial elements in adult shell crystallization is proposed. During larval development, amoebocytes accumulate copper (and possibly other elements) and store them in membrane-lined cytoplasmic granules. The gradual accrual of copper eventually endows amoebocytes with a blue-green pigmentation that makes them visible (pigment spots). Once sufficient copper is accumulated, amoebocytes are mobilized into hemolymph circulation and dispersed throughout the tissues. This coincides with, and may actually trigger, metamorphosis. Mobile amoebocytes can then migrate to the mucus of the mantle cavity and participate in shell deposition. Metal stored in amoebocyte granules may be involved in crystal formation within the amoebocyte or may be discharged onto the matrix of newly forming shell to precipitate proteins. In either case, metals are irreversibly bound in the shell as it forms and concomitantly change the shell structure from an aragonite (larval) to calcite (adult) shell.

BIOLOGIC RELEVANCE

On the assumption that high ambient and accumulated concentrations of terrestrial metals must be harmful, a perception has evolved that metals are sequestered in oysters solely to detoxify them until they are eliminated. This is not true however, for copper and zinc in eastern oysters. Much of the relevant information amassed during the last century supports a hypothesis that copper and zinc are actively captured, sequestered, and retained by oyster amoebocytes for specific physiologic purposes. These purposes may include larval setting and metamorphosis (Prytherch 1934), nutrition, and defense (Fisher 2004). Zinc, copper, and other terrestrial metals may also be essential for shell construction, as described here. If so, several aspects of oyster biology are affected.

Amoebocytes seem to have an extraordinary capacity to perform in a wide range of physiologic functions, including nutrition, defense, excretion, metamorphosis, and shell repair and deposition. This is because of their unique ability to traverse epithelial barriers and move throughout the soft tissues and shell matrix. This was emphasized by Wagge (1955):

"Growth, regeneration, and repair are other functions greatly assisted by amoebocytes and certain problems in

invertebrates are more easily resolvable if one envisages the possibility that this primitive amoebocytic transport system can move with speed to a certain area, act efficiently, and increase its numbers both from the reactivation of resting cells and by further budding or division of the appropriate tissues.” (Wagge 1955, p. 74–75)

Because of the high visibility of nutrition and defense, amoebocytes have sometimes been perceived to exist only in the alimentary tract and hemolymph. Yet, amoebocytes are active throughout the oyster, including the mucus and shell.

Importance of Terrestrial Elements

Amoebocytes have another unique characteristic, the ability to capture and store terrestrial elements at high concentrations without toxic effect. These elements may be needed at relatively high concentrations to perform various physiologic functions, including shell deposition. High concentrations of copper and zinc may be needed to provide flexibility for competing needs in defense and nutrition (Fisher 2004). High concentrations of these and other metals may also be needed for shell deposition. A balance must exist between shell growth and tissue growth, the latter being neither consistent nor predictable because it is dependent on widely fluctuating environmental factors (e.g., temperature, salinity, or food availability). If elements essential to shell growth are not available at the time of tissue growth, then opportunity is lost. If, however, high accumulations of precipitating metals are retained in reserves (amoebocytes), then the oyster could deposit new shell at every available opportunity.

The composition of shell indicates that various elements are incorporated during shell deposition, including aluminum, copper, iron, manganese, zinc (Smith and Wright 1962), cadmium, chromium, lead, and mercury (Ferrell et al. 1973). Some elements may be incorporated directly from the water column, but those at high concentrations most likely come from an internal storehouse such as the cytoplasmic granules of amoebocytes. It is not clear how many elements are stored in amoebocytes. Orton (1923) reported that copper, zinc, and tin were accumulated in the amoebocytes of *O. edulis*, whereas Galtsoff (1938, 1953, 1964) reported iron and manganese in amoebocytes *C. virginica*. The content of amoebocyte granules, despite differences in assimilation and retention, must ultimately be determined by the composition in the local environment, albeit at lower concentrations (Galtsoff 1964, Ferrell et al. 1973, Carriker et al. 1982, 1991, Simkiss 1983).

It is unknown which elements might serve to precipitate proteins in shell matrix or even serve as crystallizing nuclei. Some effects of ambient concentrations of metals have been investigated. Shuster & Pringle (1969) found excellent shell growth for oysters exposed to elevated concentrations of copper, but poor shell growth of those exposed to cadmium. Some reports have noted that oyster shells formed in polluted environments were thin, relatively flaky, or multilayered compared with oysters from less contaminated sites (Frazier 1976, Okazaki & Panietz 1981). Frazier (1976) believed that shell thinning was linked to effects of copper and cadmium on shell calcification enzymes. Although these data are few, conflicting, and largely qualitative, they could indicate that metals exert an influence on shell deposition that ultimately affects shell quality. If competent shell structure (i.e., strength and stability) depends on metal composition, then deviations in metal composition may adversely affect shell quality.

This possibility is relevant to effects of a high-profile environmental toxicant, tributyltin (TBT), which once was considered a

successful antifouling agent in marine paints. Thickened and areolar shells of *C. gigas* (Fig. 7) in the Gironde River, France, were the first warning that TBT carried a high environmental impact (Alzieu et al. 1980, 1982, Waldox & Thain 1983). TBT can impose sex changes (“imposex”) and reproductive sterility in gastropods from chronic exposures as low as 2 ng L⁻¹ (Gibbs & Bryan 1994). Alzieu (1986) believed that the effect of TBT on *C. gigas* shell was on mechanisms of calcification.

“Perturbations of the calcification mechanisms of oysters cultivated in the Atlantic Ocean have been wide-spread since 1979. The abnormal shells were thickened and their cut showed numerous chambers fill[ed] in with a jelly. . . . The components of [this] jelly do not [bind] with Ca²⁺ or with HCO₃⁻, and when added to [a] solution of CaCO₃ slow down or prevent the formation of crystals of CaCO₃.” (Alzieu 1986, pp. 1131–1132)

It may be that the jelly component observed by Alzieu was actually the conchiolin matrix deposited for new shell that could not crystallize because the normal complement of metals had been supplanted by TBT. In water exposures of eastern oysters to TBT (Fisher et al. 1999), relatively high concentrations were localized

Figure 7. *Crassostrea gigas* shells are deformed by exposure to tributyltin, an anti-fouling paint used in marine paints. *Top:* Shell cut open to show chambering in the upper valve. *Bottom:* Chambering sufficiently severe to create a ‘ball-shaped’ oyster. These malformations occur in *C. gigas*, and apparently do not occur in *C. virginica* or *Ostrea edulis*. Photographs reprinted from Alzieu (1986, Figs. 2 and 3) with permission of the author.

in amebocytes (unpublished data). Abnormal shell development found for *C. gigas* does not seem to extend to *O. edulis* (Waldock et al. 1983, Alzieu 1986) or *C. virginica* (Rice et al. 1987). It is interesting, albeit perplexing, that environmental regulations to reduce TBT in estuaries may have created a greater demand for copper-based marine antifouling paints (Claisse & Alzieu 1993). As noted before, copper may not be toxic to adult eastern oysters, but is toxic to larvae and can inhibit setting and metamorphosis at high concentrations (Prytherch 1934, Fisher 2004).

Copper Stimulation of Metamorphosis

According to Prytherch (1934), many of the physiologic changes that occur at metamorphosis are a consequence of activation by copper, which he believed oxidized glutathione and elevated cellular respiration. He postulated (p. 85) that copper in the water column was ingested into the stomachs of oyster larvae, dissociated by low pH, and then distributed, apparently via hemolymph, to various organs to stimulate metabolic activity. It is equally possible, however, that copper from the water column is gradually accumulated in the cytoplasmic granules of amebocytes. Once a threshold is surpassed, either in the amount or concentration of copper, the amebocytes are activated and disperse into hemolymph and tissues, where they may effect activation of other cells by release of copper. Prytherch (1934) described only the amebocytes that comprised the pigment spots, but amebocytes (coelomocytes) are also known to exist in the visceral cavity of larvae (Elston 1980a, Elston 1980b). These, too, may be accumulating copper during larval development and could participate in metabolic stimulation of cells. The ability of amebocytes to discharge copper to extracellular spaces (degranulation) provides a capacity to distribute the element to different cells and organs.

Metamorphosis is abrupt, rather than gradual, so it is more likely that a stimulating substance (e.g., copper), is released from highly concentrated internal stores, rather than extracted from low or variable ambient concentrations. If copper is a trigger for metamorphosis, then the amebocyte threshold for copper accumulation could represent the amount needed to ensure activation of not just amebocytes, but of all organs undergoing metamorphic change. Amebocytes, once distributed throughout oyster tissues, could distribute copper to multiple organs simultaneously. It is worth noting that copper in spawned eggs of *C. virginica* were found to contain very similar concentrations of copper (Greig et al. 1975), even

though concentrations from the parents could vary (Table 4). This implies that copper concentrations in embryos may be tightly regulated.

Influence of Freshwater Inflow on Oyster Distribution

Distribution of eastern oysters throughout the Gulf of Mexico and along the Atlantic coast is often associated with reduced salinities (Cake 1983, Soniat & Brody 1988). Reduced salinity is believed to relieve pressure from recent disease epizootics caused by *Perkinsus marinus* (Andrews & Ray 1988) and *Haplosporidium nelsoni* (Ford 1985), and from predation by drills, sponges, starfish, and other high-salinity predators that have coexisted with oysters for millennia (Loosanoff 1955, Lunz 1955, Hopkins 1956, Menzel et al. 1966). Counter to this model is the fact that eastern oysters are not always restricted to regions with reduced salinity. Beaven (1955) identified two setting patterns in the Chesapeake Bay, patterns that appear fairly consistent throughout the range of eastern oysters.

"One type occurs where rich runoff enters directly into high salinity waters producing a body of water exhibiting a fairly steep salinity gradient. Oyster beds in such areas are subject for brief periods to salinities low enough to prevent the establishment of many of the predators and fouling agents that hinder spat survival in waters of a more sustained high salinity.... A second type of high setting area consists of a semi enclosed body of water where the salinity is fairly uniform and where there is a comparatively slow rate of exchange of water overlying the oyster beds." (Beaven 1955, p. 34)

The second type of setting area resembles those described for the tidal creeks of South Carolina (Lunz 1955) and oceanic populations in Virginia and Delaware (Nelson 1955). Reduced salinity, then, is not necessarily required for oyster setting or the ultimate survival of eastern oysters.

An alternate explanation for distribution patterns of eastern oysters was implied by Prytherch (1934), who described a dependence on recurring influxes of copper from the watershed. Successful setting required that larvae were exposed to appropriate concentrations of copper at least once at maturity, if not intermittently throughout their development. Any discrepancies or deviations from this, whether stemming from tides, currents, drought, freshwater diversion, sedimentation, lack of resuspension, or the mere absence of appreciable copper in geologic deposits, would seemingly eliminate successful setting. Watershed runoff with sufficient volume (i.e., streams and rivers) can generate flows that allow oyster setting far and deep into the receiving water. But in areas of low-volume runoff, oyster setting may be restricted to sites directly adjacent to land. At these (usually intertidal) sites, copper concentrations may be maintained by proximity to its source (land) and possibly from resuspension of particulate matter.

A dependence on copper might help to explain the sometimes confusing year-to-year variability in larval settlement that has been recorded at the same locations over several years (Collins 1889, Prytherch 1929, Hopkins 1935, Andrews 1955, Beaven 1955, Nelson 1955). Successful setting would require that mature larvae, spawned at different locations and times throughout the spring and summer, must co-occur in time and space with clean substrate (cultch) and sufficient concentrations of copper in a seawater milieu. Most oyster setting areas are probably subject to day-to-day, even hour-to-hour, variability in the availability of copper.

Unlike adult oysters, larvae are susceptible to high water con-

TABLE 4.

Concentrations ($\mu\text{g g}^{-1}$ dry weight) of selected elements in adults and spawned eggs from *C. virginica* collected at two sites in Connecticut, Housatonic River (HR) and Branford (BR), as reported by Grieg et al. (1975).

Element	Site	Adults	Eggs
Cadmium	HR	28.1	<1.6
	BR	15.6	<1.2
Copper	HR	2,208	28.9
	BR	1,260	27.8
Lead	HR	<4.2	<10
	BR	7.1	<9.9
Silver	HR	12.1	<1.6
	BR	16.4	<1.2
Zinc	HR	10,460	82.4
	BR	8,300	65.9

centrations of copper (Prytherch 1934, Calabrese et al. 1977). Hence, the amount of copper available to stimulate setting and metamorphosis is critical. Prytherch (1934) found the greatest setting intensity occurred at copper concentrations that were nearly toxic. Freshwater inflows contaminated by anthropogenic activity might elevate copper, or other chemical pollutants, to concentrations that are toxic to embryos or larvae. Adult oysters may not be vulnerable because copper and other cations are probably bound in the mucus of the mantle cavity, protecting susceptible tissues (Fisher 2004). Binding in mucus would also protect amoebocytes that, *in vitro*, are sensitive to high copper concentrations (Butler & Roesijadi 2001).

Survival of spat, juvenile and adult oysters may require terrestrial elements other than copper. In fact, a copper requirement may have evolved as a surrogate to ensure that oysters settle in areas with an ample supply of terrestrial elements. Zinc is the most highly concentrated element in eastern oyster amoebocytes and may be important in phagocytosis for defense and nutrition (Fisher 2004) as well as in shell deposition. Accumulations of other elements, though not as dramatic as copper and zinc, are also quite high and may serve additional roles in oyster physiology.

Effects of Altered Freshwater Inflow

Copper, zinc, and other metals that may be critical to setting, growth, or survival of eastern oysters are provided by terrestrial runoff and river inflow to estuaries and coastal zones. How much and when these elements arrive at oyster beds may determine recruitment, health, or toxicity to oysters. Consequently, human activities that alter the availability and timing of water runoff and inflow will likely alter the health and sustainability of eastern oyster populations. Agriculture and urbanization are major activities that affect the input terrestrial metals into coastal zones and estuaries (Browder & Moore 1981). Some agricultural practices, such as deforestation, will increase the amount of sediment (and presumably elements) into the water. Other agricultural practices combine with urbanization to deplete coastal zones of fresh water. Dams and canals, whether for agriculture, drinking water, sewage disposal, or generation of hydroelectric power, alter the volume and timing of freshwater flows to estuaries.

Sammy M. Ray, widely recognized for his research with *Perkinsus marinus* disease, has often proposed retaining natural freshwater flows to reduce disease incidence in oyster-growing regions.

"Oysters will flourish only in areas where sufficient freshwater inflows occur on a regular basis." (Andrews & Ray 1988)

Whereas emphasis has been placed on avoidance of predators and disease, eastern oyster success and distribution may also be a reflection of the evolutionary advantage gained by their ability to accumulate and use high concentrations of otherwise toxic metals. Any alteration of metal availability, which occurs with alteration of the quantity or timing of freshwater flows, denies the oyster this competitive advantage.

The eastern oyster has for over a century supported a major commercial fishery. The sustainability of the resource has been severely threatened by heavy fishing pressure from the turn of the 20th century and by disease in its latter half. We have slowly realized that oysters and their habitats (reefs) provide valuable ecosystem features, including biodiversity (Wells 1961, Breitburg et al. 1995, Breitburg 1999, Posey et al. 1999), water filtration (Haven & Morales-Alamo 1970, Officer et al. 1982, Newell 1988, Harsh & Luckenbach 1999), biodeposition (Haven & Morales-Alamo 1966, Dame et al. 1984), and nutrient mineralization (Pomeroy & Haskin 1954, Dame et al. 1989, Dame & Libes 1993, Dame 1999). Because of the reliance of fish on oyster reefs for refuge and prey items, some consider oyster reefs to be essential fish habitat (Coen et al. 1999). Most states or regions with an economic or ecologic interest in oysters have already begun attempts to conserve and restore productive reefs (Luckenbach et al. 1999). The probable dependence of oyster setting, growth, and survival on copper and other terrestrial elements will influence decisions on which reefs to protect and which sites to restore.

ACKNOWLEDGMENTS

Thanks are due to Melbourne Carriker, Guri Roesijadi, Leah Oliver, Steve Jordan, and Robert Anderson for useful comments on early versions of this report. Robert S. Brown provided material from his unpublished dissertation at Johns Hopkins University. Library material was assembled by Sonya Doten and Liz Pinnell, graphic representations prepared by Stephen Embry, and translations graciously provided by Tere McMahon. Sea Grant of Maryland provided copies of Figures 1 and 4. Thanks are extended to R. Elston, C. Walker, D. Shepard, J. Fournie, L. DiMichael, W. Davis and P. Chapman for valuable discussions and information. The editor of JSR kindly allowed updates to this report after its acceptance. This was prepared in support of the Gulf Ecology Division mission in Altered Habitat, and is GED contribution #1197.

QUARANTINE OF OYSTER SHELL CULTCH REDUCES THE ABUNDANCE OF *PERKINSUS MARINUS*

DAVID BUSHEK,¹* DONNIA RICHARDSON,² M. YVONNE BOBO² AND LOREN D. COEN²

ABSTRACT Oyster shell is the preferred substrate for replanting oyster beds and restoring oyster reefs. If pathogens remain viable in tissues attached to shell, then planting shell may inadvertently serve as a vector for pathogen transmission. Limited local shell sources may exacerbate the problem by increasing the risk of spreading novel strains into new areas if shell is derived from other regions. In South Carolina, the primary source of oyster shell is currently the Gulf of Mexico, where the protozoan oyster pathogen *Perkinsus marinus* (Mackin et al. 1978) has been problematic. Although *P. marinus* is present in South Carolina waters, different strains exist in the two regions. Given the detrimental effects of *P. marinus* on oysters, protocols to minimize its spread via planting of shell are needed. We conducted a short-term, replicated experiment to follow changes in *P. marinus* abundance in oyster tissues by placing whole, intact oysters or shucked oysters in shell piles. The amount of oyster tissue present and parasite abundance declined precipitously after one month and was virtually eliminated by three months. Parasite persistence was dramatically longer in whole, unshucked oyster tissues as compared with those associated with shucked oysters. Viability of parasites after one month was, however, unclear. The results support the recommendation that the quarantine of shell for one month or more can dramatically reduce the potential risk of spreading *P. marinus* when planting oyster shell (=cultch) from other geographic areas. This recommendation is applicable to virtually any region, but several parameters such as effects of climatic conditions and shell pile configuration warrant further investigation as does the persistence of other pathogens on shell piles.

KEY WORDS: Dermo, disease transfer, oyster, *Perkinsus*, quarantine, restoration, SC, shell planting

INTRODUCTION

It is now widely recognized that oyster reefs are valuable habitat for a wide variety of organisms (Coen et al. 1999, Luckenbach et al. 1999) and that oyster resources can be enhanced through directed oyster reef restoration programs (Coen & Luckenbach 2000). As a result, oyster reef restoration programs have expanded rapidly throughout the United States in recent years. Unfortunately, oyster shell needed to rebuild reefs is generally scarce in those areas where restoration is needed most. Alternatives to shucked oyster shell cultch include clam shell, whelk shell, coal ash by-products, fossil shell, old porcelain material, marl (sedimentary CaCO₃), and similar materials (Luckenbach et al. 1999), but the reef-building material of choice is oyster cultch (Coen & Luckenbach 2000, and references therein). The most economical source of plentiful shell for restoration programs along the Atlantic coast of the United States is from the Gulf of Mexico. A major question related to the use of out-of-state shell is its potential to function as a vector of disease and non-native species, especially at a time when invasive species and new disease strains are being introduced around the globe (e.g., see Mann 1983, Naylor et al. 2001, Chapman et al. 2003, NAS 2003).

One potential risk of using oyster cultch from the Gulf of Mexico for replanting and restoring beds and reefs on the Atlantic Coast is the protozoan oyster pathogen *Perkinsus marinus*, which causes dermo disease in the Eastern oyster *Crassostrea virginica* (Gmelin, 1791). This parasite is abundant throughout the Gulf of Mexico (Soniati 1996) and along the Atlantic Coast (Burreson & Ragone Calvo 1996, Ford 1996, Bobo et al. 1997), but different strains inhabit or are predominant in different regions (Bushek & Allen 1996, Reece et al. 1997, Reece et al. 2001). The introduction of additional, possibly more virulent, parasites is a real threat to

any state's oyster populations. Therefore, the development and use of protocols that minimize the survival or persistence of *P. marinus* is warranted.

Little information exists concerning the survival of pathogens on cultch (shell) or the treatment of cultch prior to replanting to prevent the transmission of diseases. Preliminary work revealed that desiccated tissues (adductor muscle) found attached to oyster shell sampled from a large shell pile in Louisiana contained *P. marinus* parasites—putatively identified via body burden assay (Bushek et al. 1994) with Ray's fluid thioglycollate medium (RFTM) (Ray 1966). Subsequently, a sample of fresh shell (aged less than one month) on a shell pile from South Carolina contained whole intact oysters (i.e., not shucked) and dehydrated tissues as above on single valves. Large oysters (>50 mm) contained 12.7 parasites per gram, whereas smaller oysters, which were more commonly found whole and intact, contained 44 parasites per gram wet tissue (Bushek 1997, Bushek 1998). Though these parasite numbers are not particularly high, Mackin (1962) reported that 100–500 cells could initiate an infection, whereas Valiulis (1973) reported the initiation of infections with as few as ten cells. It is entirely possible that the number of parasites had already declined substantially in the oysters examined by Bushek (1997, 1998) while on the shell piles before collection, but the initial infection intensities of the oysters examined were unknown. Furthermore, there was no way to ascertain the viability of the parasites. If those parasites detected are not viable, then they pose no threat to populations where the shells are planted. On the other hand, viable parasites moved with shells planted to restore or enhance oyster populations could actually exacerbate oyster production problems simply by increasing the number of parasites available to infect oysters.

In light of these observations, we undertook an experimental study with the following four objectives: (1) to monitor the persistence or elimination of *Perkinsus marinus* surviving in tissues that remain attached to oyster shell in shell piles; (2) to compare *P.*

*Corresponding author. E-mail: bushek@hsrl.rutgers.edu

marinus persistence in shucked oysters versus whole (initially live, unshucked) oysters (the worst-case scenario); (3) to provide better guidance on how to treat imported shell to protect local oyster resources; and (4) to make management recommendations as appropriate.

MATERIALS AND METHODS

This study applied an experimental approach using small (approximately 100 U.S. bushel) shell piles constructed by South Carolina Department of Natural Resources (SCDNR) Marine Resources Division and seeded with *Perkinsus marinus* infected oysters from the Gulf of Mexico. Ninety *P. marinus*-infected oysters (mean shell height \pm 1 SD = 74.8 \pm 11.1 mm) were collected from Confederate Reef, West Galveston Bay, Texas, on March 19, 2002, and shipped overnight to SCDNR's Marine Resources Research Institute in Charleston, South Carolina. At the time of collection, salinity was 26 psu and surface water temperature was 25°C. Shell height and whole weight were recorded for each oyster. On March 22, 2002, 45 oysters were shucked, wet meat weight determined, and the meats divided into two equal samples. Care was taken to divide tissues equally during all dissections. One half of the soft tissues were removed for time zero sampling and the other half was returned to the valves which were then loosely held together with rubber bands to form a container for placement in experimental shell piles as described below.

Time zero samples (March 22, 2002) were further divided into three equal samples, each comprising about one-sixth of the entire oyster. One portion was processed for *P. marinus* body burden analysis using standard protocols (Bushek et al. 1994, Fisher & Oliver 1996). The second portion was processed identically, except without the RFTM incubation step for reasons outlined below. The third portion was used to determine tissue dry weight.

The non-RFTM incubation sample was used as a conservative validation of parasite viability. During RFTM incubation, viable *P. marinus* enlarge forming a prezoosporangium that possesses a NaOH-resistant cell wall (Choi et al. 1989) and stains blue-black with Lugol's iodine (Ray 1952). The total number of *P. marinus* cells in the entire oyster was then estimated from the number of prezoosporangia present in the sample processed for body burden analysis with RFTM incubation. We assumed that enlargement in RFTM indicated cell viability at the time of sampling. Nonviable cells do not enlarge or develop the NaOH-resistant cell wall and are therefore digested during the NaOH incubation step. It is possible, however, that some *P. marinus* parasites form prezoosporangia in moribund and decaying oyster tissues (Ray 1954, Mackin 1962), but this phenomenon is poorly documented, and the viability of such cells is unknown. By processing a portion of each oyster with RFTM and a portion without RFTM incubation, we attempted to determine the proportion of parasites that were responding to the RFTM and therefore viable. The viability of any parasites that enlarged prior to RFTM incubation could not be determined. Hence, our estimate of viability was conservative.

Three experimental piles (each roughly 100 U.S. bushels) were constructed from existing sources of recently shucked Gulf and South Carolina oyster shell. In March 2002, three replicate plastic mesh bags, each containing five whole, unshucked oysters and five of the shucked oysters processed above, were buried approximately 0.5-m deep in each shell pile. Oysters were assigned to treatments (shucked or whole) and to bags based on size to ensure an approximately equal size distribution for subsequent sampling. The total number of parasites added to each pile via shucked or

whole unshucked oysters was estimated from the body burden samples taken above. Because only half of the tissue from shucked oysters was added to shell piles, the total number of parasites added to a pile in shucked oyster tissues was calculated as half the sum of the total body burden estimates. We assumed parasite burdens were similarly distributed among whole unshucked oysters. Because whole unshucked oysters were randomly distributed within size classes, we assumed that each pile received an equivalent number of parasites in total from these oysters. StowAway temperature data loggers from Onset Corporation were deployed within the piles to monitor internal temperature logging every 30 min. A fourth data logger recorded air temperature at the site for a portion of the experiment.

One bag was selected and removed from each pile after 31, 73, and 115 days (Fig. 1) to quantify and process remaining tissues for *P. marinus* body burden as described above with the following differences. On day 31 (April 22, 2002), tissues remaining in shucked oysters were divided into two equal samples and processed for *P. marinus* body burden, one with RFTM incubation and one without as described above. These samples were considered to represent 25% of what would have remained had the entire oyster been placed in the pile. Whole oysters were shucked and tissues divided into three equal portions for RFTM body burden analysis, non-RFTM body burden analysis and dry weight determination. On day 73 (June 3, 2002), samples were processed identically to day 31 except dry weight was not determined; instead, one portion was used in an attempt to isolate and culture *P. marinus in vitro*. Parasites were purified as described by Chu and La Peyre (1993) and cultured as described by Dungan and Hamilton (1995). On day 115 (July 15, 2002), samples were processed similarly except whole oysters were divided into two samples only for RFTM and non-RFTM *P. marinus* body burden estimation. Temperature loggers were downloaded each time that oysters were sampled and then redeployed.

Data were analyzed by comparing descriptive statistics and plots of relevant parameters over time for shucked and unshucked oysters. A three-way analysis of variance (ANOVA) was used to determine if oysters differed in size among treatments (shucked or unshucked), replicate piles or bags sampled from piles. Following

Figure 1. Schematic of the experimental design. $n = 90$ oysters. Forty-five oysters (partially shaded) were shucked and half of the meat removed for analysis at the start of the study. Completely shaded oysters were placed into shell piles as whole live oysters. Five whole and five shucked oysters were sampled from each pile at each sampling interval.

Figure 2. Internal temperatures (symbols) of three shell piles and external temperature (solid line, measured after June 2002) adjacent to the piles measured at 30-min intervals during the study period. Dotted line represents the mean internal temperature of all piles. Dashed line indicates the mean external temperature.

\log_{10} transformation of RFTM counts and assignment of oysters to the various shell piles, mean total body burdens were compared among shell piles. With shell piles as replicates, one-way ANOVAs were also used to compare counts of putative *P. marinus* in RFTM and non-RFTM assays for each treatment on each date. All statistics were carried out using SYSTAT 8.0.

RESULTS

A three-way analysis of variance indicated no significant differences among mean sizes of oysters in bags, piles, or treatments ($P \geq 0.05$ all effects and interactions). Temperature within the piles fluctuated between 6°C and 38°C, with little difference among the piles: means were 21.95°C, 21.83°C, 21.85°C, respectively (Fig. 2). When measured concurrently during the final month of the experiment, temperatures within the three shell piles were cooler on average and less variable than surface temperature (Fig. 2). Temperatures within the piles ranged from 18°C to 37°C with a mean of 25°C, whereas temperatures on the surface ranged from 16°C to 47°C with a mean of 27.5 (Fig. 2). Fluctuations were related to both diurnal (day/night) and climatic changes (e.g., fronts) with external fluctuations always exceeding internal fluctuations. Initial (time zero) RFTM assays indicated 100% prevalence of *P. marinus*. RFTM body burden estimates of *P. marinus* abundance ranged from 180 parasites per oyster to 27.8×10^6 parasites per oyster with a median infection intensity of 95,760 parasites per oyster. Summing RFTM estimates of total body burdens from oysters added to specific piles, and assuming that the portion of tissue added to each pile (i.e., not sampled at time zero) contained half of the total body burden, indicated that 15.8×10^6 parasites were added to pile one, 26.5×10^6 parasites were added to pile two, and 14.0×10^6 parasites were added to pile three for a total of 56.3×10^6 parasites. A one-way ANOVA on \log_{10} -transformed estimates from individual oysters indicated that mean body burdens were not significantly different among piles ($P = 0.513$). Assuming a similar distribution of parasite loads in the 45 un-

shucked oysters, a total of 112.6×10^6 *P. marinus* parasites were present at the start of the experiment in the whole unshucked oysters and about 37.5×10^6 parasites (one-third of the total) were added to each pile in whole unshucked oysters.

Oyster tissues decomposed over time and total parasite abundance declined rapidly (Figs. 3 and 4). After 31 days, only 2 of 15 (13%) shucked oysters contained any tissue (Table 1) and the RFTM assay indicated only 216 parasites remained in tissues from these oysters. No shucked oysters contained any tissue in subsequent samples. In contrast, 12 of 15 (80%) whole oysters contained tissue after 31 days, 10 of 15 (67%) after 73 days, and 2 of 15 (13%) after 115 days (Table 1). The RFTM assay indicated *Perkinsus* abundance dropped 99% by day 31 and declined to only

Figure 3. Change in mean wet weight (g) of recoverable tissue in shucked (dashed line) and unshucked (solid line) oysters after 0, 31, 73, and 115 days in shell piles. Error bars represent ± 1 SEM for the three experimental shell piles.

0.005% of the original abundance by day 115 (Fig. 4). Attempts to isolate and culture *P. marinus* *in vitro* after 2 mo failed.

At time zero, the number of *P. marinus* detected in the non-RFTM assay (18,000 in all oysters) was significantly less than the number detected in the RFTM assay (112.6×10^6 , $P < 0.009$, one-way ANOVA). In all subsequent samples, there were no significant differences between parasites enumerated in RFTM or non-RFTM assays ($P > 0.196$ for all dates). Abundances were unexpectedly higher on day 73 compared with day 31 in both RFTM and non-RFTM assays for whole unshucked oysters due to two oysters with high numbers of apparently unenlarged (5–20 μm) parasites. During RFTM incubation, parasites typically enlarge to 40 μm or more, and observers noted their uncertainty in classifying these unusually small cells as *Perkinsus* while counting them, but small size and microscopic examination was insufficient to disregard them.

DISCUSSION

Considering that *Perkinsus marinus* continues to plague *Crassostrea virginica* throughout most of the oyster's distribution along the Gulf and Atlantic Coasts of the United States, it is only prudent to minimize the spread and proliferation of *P. marinus* whenever possible. A long-standing recommendation about planting oyster seed where *P. marinus* has been problematic is to avoid the use of *P. marinus* infected seed (Andrews & Ray 1988). Though this may seem to be simple common sense, it is not always followed and, to

TABLE 1.

Number of shucked (S) and unshucked (U) oysters with recoverable tissue remaining in shell piles over time.

Total	2	0	0	12	10	2

our knowledge, has never been incorporated into the hygiene of handling cultch before it is planted to collect oyster spat. This study demonstrated that *P. marinus* abundances can be high on fresh cultch, but may decline rapidly (within 1–3 mo) in shell piles. Thus, short-term (1–3 mo) shell pile quarantine may reduce or even eliminate the potential reintroduction and subsequent spread of *P. marinus* when shell is planted to replenish, rebuild, or restore oyster reefs and beds. Nonetheless, several parameters need further exploration.

Not surprisingly, tissue decomposition and parasite decline were faster in shucked animals, most likely because the whole unshucked oysters remained alive for some period in the shell piles. Therefore, whole oysters represent the "worst case scenario" and should be used to establish minimum quarantine duration. Interestingly, except for time zero, the non-RFTM assay revealed concentrations of putative *P. marinus* throughout the study similar to those in the RFTM assay. The lack of significant differences between these samples indicates that the parasites counted in the RFTM assay had likely enlarged in the decomposing tissues prior to RFTM incubation. Unfortunately, the viability of these parasites could not be determined. It is generally assumed that only *Perkinsus* species respond to RFTM incubation by enlarging and developing a thick cell wall that stains blue-black with iodine and is resistant to 2 M NaOH. Furthermore, so far as we are aware, no organisms have been reported from oyster tissues that stain blue-black with Lugol's iodine other than *Perkinsus* spp. It is possible, however, that some of the cells detected with the non-RFTM assay were not *Perkinsus*. Regardless, there were several orders of magnitude fewer parasites on each sampling date after the start of the experiment.

The shell piles used were relatively small (around 100 U.S. bushels) and oysters were buried only 0.5-m deep. This size is reasonable for reef restoration programs in South Carolina (e.g., S.C.O.R.E., www.eso.noaa.gov/scoysters), but is likely much smaller than shell piles produced by commercial shucking operations in other states and used for larger restoration efforts or to replant harvested beds. Decomposition rates are likely to decrease with the size of the shell pile, and we suspect that the abundance of *P. marinus* is closely correlated to decomposition rates of tissue as apparent in this study. It is also likely that decomposition rates are correlated with temperature. Hence, tissue decomposition on shell piles in cooler climates or during cooler portions of the year is apt to be reduced and may increase survival time of *P. marinus* in tissues on the pile.

Thus, though we recommend that shell be quarantined on land for at least a month if not longer, it is clearly apparent that a number of factors should be investigated further. These include temperature and seasonal effects, moisture in the form of humidity or rainfall, and the viability of *P. marinus* in tissues over time. Finally, quarantine impacts for other known or potential oyster pathogens and for human pathogens that are associated with oysters should be investigated similarly.

ACKNOWLEDGMENTS

The authors thank Dr. Sammy Ray for collecting infected oysters and Jennifer Foster for assistance with RFTM and non-RFTM processing and enumeration of *Perkinsus*. Staff from the SCDNR MRD OFM assisted with shell procurement and shell pile construction. An anonymous reviewer provided comments that

improved the manuscript. Financial support was provided by SCDNR's Marine Resources Division to the Marine Resources Research Institute and by other state funding. This is contract no. 540 of the Marine Resources Research Institute, SCDNR; contri-

bution no. 1382 of the Belle W. Baruch Institute for Marine Sciences and Coastal Research, USC; and contribution no. 2004-3 of the Institute of Marine and Coastal Sciences, Rutgers, The State University of New Jersey.

EFFECTS OF SALINITY ON GROWTH AND SURVIVAL OF SILVER-LIP PEARL OYSTER, *PINCTADA MAXIMA*, SPAT

JOSEPH J. TAYLOR,² PAUL C. SOUTHGATE¹* AND ROBERT A. ROSE³

¹Pearl Oyster Research Group, School of Marine Biology & Aquaculture, James Cook University, Townsville, Queensland 4811, Australia; ²Atlas Pacific, North Fremantle, W.A. 6159, Australia (Current address); ³Pearl Oyster Propagators Pty. Ltd., 4 Daniels St., Ludmilla, N.T. 0820, Australia

ABSTRACT Juvenile silver-lip pearl oysters, *Pinctada maxima* Jameson, were held over a period of 20 days in the following salinities: 45, 40, 34 (ambient), 30, and 25 parts per thousand (‰). There were no significant differences in survival of spat from the different treatments; however, growth was significantly depressed at salinities of 45‰, 40‰, and 25‰. Best growth was recorded at a salinity of 30‰ where spat were significantly larger than those held at ambient salinity. Results indicate that *P. maxima* spat are tolerant of a wide range of salinities; moreover, reduced salinity may be beneficial to growth.

KEY WORDS: salinity, growth, survival, pearl oyster, *Pinctada maxima*

INTRODUCTION

Salinity is a major environmental factor determining the distribution of bivalve molluscs (Hummell 1980, Fuersich 1993). Changes in salinity bring about a broad range of physiologic responses in bivalves and have been shown to influence filtration rate (Riva & Masse 1983, Villiers et al. 1989), oxygen consumption (Bernard 1983), electrolyte balance (Natochin et al. 1981) and the rate of particle transport over the gills (Paparo 1981, Paparo & Dean 1982). Clearly, given these responses, salinity may have a major impact on growth and survival of cultured bivalves.

Salinity tolerances of a number of commercially important bivalves such as the scallops, *Pecten fumatus* (Nell & Gibbs 1986); *Argopecten irradians* (Mercaldo & Rhodes 1982) and *Argopecten ventricosus-circularis* (Singnoret-Brailovsky et al. 1996); oysters, *Ostrea angasi*, *Saccostrea commercialis* (Nell & Gibbs 1986); *O. edulis* (Castagna & Chanley 1973) and *Crassostrea virginica* (Anderson & Anderson 1975); and mussels, *Mytilus edulis planulans* (Nell & Gibbs 1986) have been determined. Similar research with pearl oysters has been conducted with adult *Pinctada fucata* (Alagarwami & Victor 1976) and *P. fucata martensii* (Kafuku & Ikenoue 1983), and with the larvae of *P. margaritifera* (Doroudi et al. 1999).

The silver-lip (or gold-lip) pearl oyster, *Pinctada maxima*, supports a lucrative cultured pearl industry along Australia's northern coastline. *P. maxima* is found predominantly in oceanic tropical waters of the Indo-Pacific where salinity approximates 35‰ (Gervis & Sims 1992). However, *P. maxima* is often cultured in near-shore estuarine areas that are subject to fluctuating salinity as a result of heavy seasonal rains. For example, pearl oyster cultivation sites in the Northern Territory of Australia experience heavy annual rainfall during the rainy season that may reduce salinity to less than 30‰ for periods of 2 weeks or more (Taylor & Rose, unpublished data, 1993–1996). There is scant information on the effects of environmental fluctuations, such as salinity, on growth and survival of *P. maxima*. This is particularly the case for juveniles that may be more sensitive to environmental change. A prior study reported that increased (to 45‰ and 40‰) and reduced (to 20‰ and 25‰) salinities were an effective means of promoting detachment of *P. maxima* spat (Taylor et al. 1997). Exposure of spat to all four salinities for up to 24 h resulted in significantly

greater detachment than recorded at ambient salinity (34‰), but did not result in mortality. This paper reports on the effects of prolonged exposure to elevated and reduced salinity on growth and survival of *P. maxima* spat.

MATERIALS AND METHODS

After 2 weeks of nursery culture, 45 day-old hatchery-reared *P. maxima* juveniles were returned to the hatchery. They were placed in a 500-L fibreglass tank with a flow-through sea water supply, nominally filtered to 5 µm. Juveniles were fed a mixed micro-algal diet composed of *Chaetoceros muelleri*, *Pavlova salina*, and *Isochrysis* aff. *galbana* (clone T.ISO) for 7 days prior to the start of the experiment. Micro-algae were cultured at 24 °C at a salinity of 34‰ using f/2 medium (Guillard 1972) and subject to a 14:10 h light:dark cycle.

Four treatments and a control, each with 5 replicates, were prepared using gently aerated 1-L plastic aquaria. All seawater used in the trial was nominally filtered to 5 µm. Ambient salinity (control) was 34‰. In two of the treatments, salinity was increased to either 40‰ or 45‰ by adding natural sea salts to seawater. In another two treatments salinity was decreased to either 30‰ or 25‰ by adding rainwater to ambient seawater.

Five *P. maxima* spat were placed into each aquarium. The mean (±s.d.) antero-posterior shell length and dorso-ventral shell height of spat at the start of the experiment were 4.6 ± 0.4 mm and 3.2 ± 0.3 mm, respectively. Spat were fed daily on a mixed micro-algal diet composed of *C. muelleri*, *P. salina*, and T.ISO. The initial ration was 100,000 cells mL⁻¹ day⁻¹ which was gradually increased to 150,000 cells mL⁻¹ day⁻¹ by the end of the experiment. Ten and 20 days after the start of the experiment, surviving spat were counted and measured for shell length and shell height. On day 20, surviving spat were again measured then dried in an oven at 50 °C for 48 hours prior to dry weight determination.

Data Analysis

Shell length, shell height, dry weight, and survival data were compared using ANOVA (Sokal & Rohlf 1981) and means were compared using Fisher's protected least significant difference (PLSD) test from the StatView statistical program, version 4.5, for Macintosh computers (Abacus Concepts, StatView, 1992). Homogeneity of variances was confirmed using Cochran's test (Snedecore & Cochran 1967).

TABLE 1.

Mean (\pm s.e.) percentage survival of *P. maxima* spat cultured at different salinities for 10 and 20 days. Values in each column with the same superscript are not significantly different ($P < 0.05$).

Salinity (%)	Percentage of Surviving Spat	
	Day 10	Day 20
45	52.0 \pm 8.0 ^a	44.0 \pm 14.0 ^a
40	76.0 \pm 32.0 ^a	60.0 \pm 20.0 ^a
34	72.0 \pm 10.0 ^a	64.0 \pm 16.0 ^a
30	64.0 \pm 8.0 ^a	44.0 \pm 8.0 ^a
25	68.0 \pm 6.0 ^a	64.0 \pm 8.0 ^a

RESULTS

There were no significant differences ($P > 0.05$) in survival between treatments on either day 10 or day 20 (Table 1). There were, however, significant differences in size between treatments on both occasions. On day 10, spat with the largest mean (\pm s.e.) shell length and shell height were those cultured at salinities of 30‰ and 34‰. At these salinities, there were no significant differences in size ($P > 0.05$); however, both groups of spat were significantly larger ($P < 0.01$) than spat in any other treatment (Fig. 1). By day 20, spat cultured at a salinity of 30‰ had a significantly greater ($P < 0.01$) shell height than spat in all other treatments where shell height did not differ significantly (Fig. 1). Mean shell length of spat cultured at a salinity of 30‰ was significantly larger

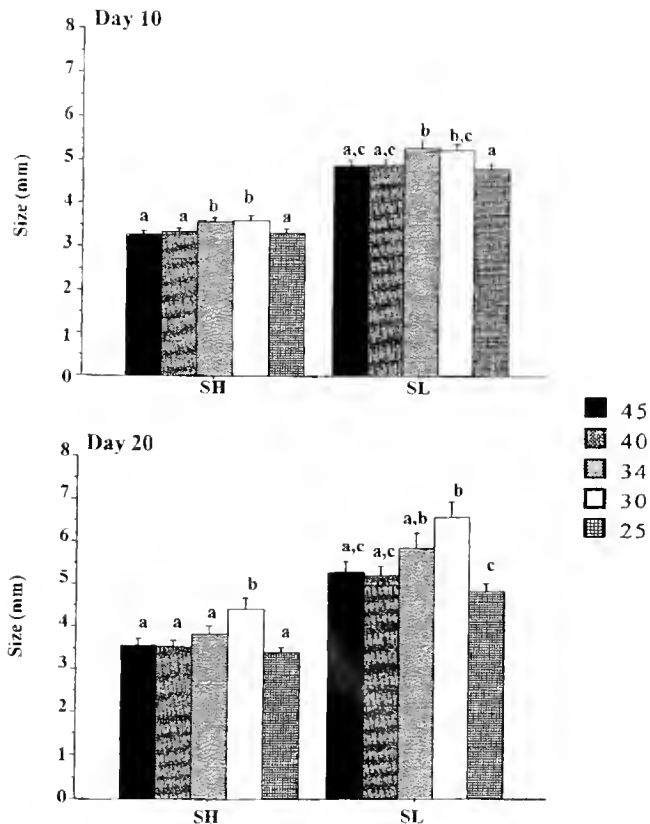

Figure 1. Mean (\pm s.e.) shell height (SH) and shell length (SL) of *P. maxima* spat cultured at different salinities (25‰, 30‰, 34‰, 40‰, and 45‰) for 10 and 20 days. SH and SL values at each time interval with the same superscript are not significantly different ($P > 0.05$).

Figure 2. Mean (\pm s.e.) dry weight (DW) of *P. maxima* spat cultured at different salinities (25‰, 30‰, 34‰, 40‰, and 45‰) for 20 days. Means with the same superscript are not significantly different ($P > 0.05$).

($P < 0.01$) than that of spat cultured at salinities of 45‰, 40‰, and 25‰ but did not differ significantly ($P > 0.05$) from that of spat cultured at a salinity of 34‰ (see Fig. 1). The mean shell length of spat held at a salinity of 34‰ did not differ significantly ($P > 0.05$) from those cultured at salinities of 45‰, 40‰, or 25‰. However, dry weight of spat cultured at a salinity of 30‰ was significantly greater ($P < 0.05$) than that of spat held at any other salinity (Fig. 2). Spat cultured at a salinity of 34‰ had a significantly greater ($P < 0.05$) mean dry weight than those cultured at salinities of 45‰, 40‰, or 25‰ that did not differ significantly ($P > 0.05$) from each other.

DISCUSSION

Salinities tested in this study had no significant effect on survival of *P. maxima* spat; however, reducing or increasing salinity significantly affected growth. Reducing salinity to 30‰ significantly improved spat growth, whereas a further reduction to 25‰ or an increase to 40‰ or 45‰ reduced growth. The tolerance of *P. maxima* spat to changes in salinity seems to be greater than that suggested for some oceanic bivalves. The scallop *Pecten fumatus*, for example, has limited tolerance to hypersaline seawater. Within 24 hours of exposure to salinities above 40‰, mantle retraction and gaping have been reported (Heasman et al. 1994) and death occurred in both spat and adult *Pe. fumatus* exposed to such salinities for 48 hours (Heasman et al. 1994, Nell & Gibbs 1986). Rapid decline in the growth rate of *P. maxima* spat cultured at salinities of 30‰ and 25‰ suggests a sharp cut-off point between a reduced salinity that improves growth and one that retards growth. It may be that salinities below 30‰, such as those that occur in parts of northern Australia during the rainy season (Hoppley 1982), may detrimentally effect growth rates of *P. maxima* spat. Such effects may be compounded by the associated run-off from shore and silt and other effluent that may influence coastal pearl oyster culture sites.

Salinity at a pearl oyster (*P. fucata*) culture site in India has been reported to range from approximately 15‰ to 37‰ (Victor, 1983). Such reduction in salinity did not cause mortality of *P. fucata*, which has broad salinity tolerance. Dholakia et al. (1997),

for example, showed that *P. fucata* is able to survive at salinities ranging from 12‰ to 70‰ when salinity change was gradual (2‰ per day). However, the same study also reported that rapid decrease in salinity, from 55‰ to 15‰, resulted in more than 60% mortality. In a similar study, Jayabhaskaran et al. (1983) reported a relationship between salinity and growth of *P. fucata*, with greater growth rates recorded at "higher" salinity (35‰). Numaguchi and Tanaka (1986) reported that the 'vitality' of *P. fucata martensii* spat decreased sharply at a salinity of 15.2‰ and high mortality resulted when salinity was further reduced to 11.4‰. Numaguchi and Tanaka (1986) concluded that the optimum salinity for culture of *P. fucata martensii* spat was >22.7‰.

The results of this study show that *P. maxima* spat are capable of survival for prolonged periods at salinities ranging from 25‰ to 45‰. They further show a significant influence of salinity on the growth rate of *P. maxima* spat and indicate that the most appropriate salinity range for nursery rearing of *P. maxima* spat is between 30‰ and 34‰. Pearl oysters must reach a minimum shell height before they can be used for pearl production (Pit & Southgate 2003) and this non-productive period is approximately 18 to 24 month for *P. maxima*. It is clearly desirable to minimize this period thereby reducing farm costs and maximizing profitability. Given the influence of salinity on the growth rate of *P. maxima* spat, the results of this study have clear implications for the positioning of nursery culture sites for *P. maxima*.

WIDESPREAD NULL ALLELES AND POOR CROSS-SPECIES AMPLIFICATION OF MICROSATELLITE DNA LOCI CLONED FROM THE PACIFIC OYSTER, *CRASSOSTREA GIGAS*

DENNIS HEDGECOCK,* GANG LI, SOPHIE HUBERT, KATHERINE BUCKLIN AND VANESSA RIBES

University of Southern California, Department of Biological Sciences, Los Angeles, California 90089

ABSTRACT Non-amplifying, PCR-null alleles are detected at 49 (51%) of 96 microsatellite DNA markers tested for Mendelian segregation in three families of the Pacific oyster *Crassostrea gigas* Thunberg. The average frequency of null alleles among F₁ hybrid grandparents is 0.093. The frequency of null alleles suggests a high level of sequence polymorphism in PCR primer-binding sites and yields a conservative estimate of one single nucleotide polymorphism (SNP) every 82 base pairs. Among 86 markers tested on congeneric species, 83 (96.5%) are likely to be useful markers for the Portuguese oyster *Crassostrea angulata*, 71 (82.6%) for the Kumamoto oyster *C. sikamea*, 31 (36.0%) for the Suminoe oyster *C. ariakensis*, and only 11 (12.8%) for the Eastern oyster *C. virginica*. PCR product-yield and mean numbers of alleles per locus also decline significantly across this series of congeneric species, which separated from the Pacific oyster <1, ~2, ~4, and >5 million years ago, respectively. Decline in cross-specific PCR yield does not depend on microsatellite repeat-motif but is correlated with the frequency of null alleles across loci. The high nucleotide diversity suggested by these observations for the oyster may be a by-product of high fecundity, consistent with G. C. Williams' (1975) Elm-Oyster evolutionary model and experimental evidence for a high mutational load. Microsatellite loci should be identified *de novo* for each species of cupped oyster, and their inheritance should be validated before use in population analyses. Homology of microsatellite loci among related species should be confirmed by sequencing of flanking regions.

KEY WORDS: Pacific oyster, microsatellite DNA, null alleles, cross-specific amplification, nucleotide polymorphism, *Crassostrea gigas*

INTRODUCTION

With the completion or impending completion of genome sequences for the human, fruit fly, nematode, mouse, and other eukaryotic genetic models, much attention is being paid to DNA sequence polymorphism and its potential use in understanding the genetic basis of complex phenotypes, such as disease susceptibility (Zwick et al. 2000). Whereas nucleotide diversity is becoming very well described for model organisms, which are all low-fecundity species (<10₃ – 10₄ eggs per female), little is known about DNA polymorphism in high-fecundity species (>10⁶ eggs per female). We might expect highly fecund species to have high nucleotide diversity, owing to large population sizes, and perhaps higher mutation rates. Indeed, G. C. Williams (1975) argued with his Elm-Oyster Model that highly fecund species with high early mortality (Type-III survivorship) should reproduce sexually, show tremendous variation in individual fitness, and carry a large load of recessive deleterious mutations.

A large load of recessive deleterious mutations has recently been confirmed for the European flat oyster *Ostrea edulis* (Bierne et al. 1998) and the Pacific oyster *Crassostrea gigas* Thunberg (Launey & Hedgecock 2001, Bucklin 2002). Oysters naturally carry dozens of highly deleterious recessive mutations, which explain widespread observations of heterosis for fitness-related traits in bivalve mollusc species, at the whole organism and genetic-marker levels, and distortions of Mendelian segregation ratios at marker loci (Launey & Hedgecock 2001). On a practical level, discovery of genetic load in bivalves suggests that marker inheritance and linkage should be confirmed early in larval development, before selection can substantially distort genotypic proportions. Typing 11-day-old larvae and using double-hybrid crosses to reduce homozygosity by descent and inbreeding depression in mapping families, Hubert & Hedgecock (2004) have produced the first low-density microsatellite DNA marker maps for the Pacific oyster.

Microsatellite DNA markers are short tandem repeats of nucleotide motifs, 2 to 6 base pairs (bp) in length, which are distributed throughout the genome in prokaryotes and eukaryotes (Chambers & MacAvoy, 2000). Because they are highly polymorphic, microsatellites have been widely used as genetic markers for studies of linkage, kinship, and population structure (Goldstein & Schlötterer 1999, Chambers & MacAvoy 2000). Presently, the DNA sequences of 369 microsatellite containing clones from *C. gigas* are deposited in GenBank. Of these, 123 have been developed into PCR-amplifiable markers with confirmed inheritance (Magoulas et al. 1998, Huet et al. 2000, McGoldrick et al. 2000, Li et al. 2003, Sekino et al. 2003) and 100 have been placed on linkage maps for the Pacific oyster (Hubert & Hedgecock 2004). Here, we present data on polymorphism of 96 of these microsatellite DNA markers and show that there seems to be little or no dependence of polymorphism on repeat-motif or motif complexity.

In developing microsatellite markers for constructing a linkage map of the Pacific oyster, we also uncovered two lines of evidence that nucleotide diversity and rate of sequence evolution in cupped oysters may be extremely high. Because high nucleotide diversity has important implications for future genetic and genomic studies with oysters, we present these findings here. First, we show that there is a high frequency of nonamplifying PCR null alleles, which likely result from polymorphism in the nonrepetitive flanking sequences to which PCR primers are designed to anneal. The inheritance of these null alleles is confirmed in multigenerational families, which were derived from the same population from which the microsatellite markers were cloned. Second, we show a dramatic decay in ability to amplify these markers across a series of four congeneric species that diverged from the Pacific oyster from <1 to >5 million years ago. This decay in cross-species amplification is independent of microsatellite repeat-motif but is correlated with the frequency of null alleles across loci. These observations contrast sharply with reports of success in amplifying microsatellites from very divergent vertebrate taxa (Garza et al. 1995, Pépin et al. 1995, Schlötterer et al. 1991, FitzSimmons et al. 1995, Rico et al.

*Corresponding author. Email: dhedge@usc.edu

1996) and species groups of *Drosophila* flies (Colson et al. 1999, Huttunen & Schlötterer 2002).

MATERIALS AND METHODS

Microsatellite Markers

Inheritance and polymorphism of 96 microsatellite markers was determined for three, multigenerational families that were used to construct linkage maps for the Pacific oyster (see Hubert & Hedgecock 2004). Of the markers that were mapped, 79 come from Li et al. (2003) and 17 come from previous publications (13 listed in Table 1 plus *cmrCgi61*, *cmrCgi41*, *um2Cgi10*, and *um2Cgi48*; Magoulas et al. 1998; Huvet et al. 2000; McGoldrick et al. 2000; see Hubert & Hedgecock 2004). Eighty-six of the 96 markers were further tested in cross-specific PCR amplifications.

Polymorphism and Nonamplifying Null-Allele Frequencies in *C. Gigas*

The *C. gigas* used for this study were F₂ or F₃ hybrid parents of the three mapping families, (7 × 6) × (5 × 2), (2 × 5) × (7 × 9), (7 × 9) × (2 × 5), their F₁ grandparents (or, for hybrid line 7 × 6, the F₁ great-grandparents), and other individuals from inbred lines under investigation (Bucklin 2002, Hubert & Hedgecock 2004). These lines were derived from the same Dabob Bay, WA, population, from which the microsatellite DNA clones were obtained (Li et al. 2003). DNA of the F₁ individuals was available from a previous study (Launey & Hedgecock 2001). Whereas families 2 × 5 and 5 × 2 share great grandparents (from inbred lines 92-2 and 89-5, respectively), families 7 × 6 and 7 × 9 are descended from lines 89-7 and 93-7, respectively, and are unrelated.

We typed the eight F₁ grandparents or great-grandparents of these four families to estimate the observed proportion of heterozygous individuals per locus, H_o , and the number of alleles per locus, n_a . Null alleles, which are included in n_a , were identified and confirmed by segregation analysis in mapping families. The

minimum number of independent null alleles per locus ($\#null$ in Table 1 and Table 1 of Li et al. 2003) was tallied by tracing allele pedigrees back to inbred great-grandparents (for families 2 × 5 and 5 × 2) or, when allele pedigrees were incomplete (for 7 × 9 and 7 × 6), by assuming that multiple null alleles at a locus were identical by descent. Differences in H_o (aresine square-root transformed), n_a , and $\#null$ among classes of microsatellite motifs were tested by ANOVA. Repeat-motifs were classified as di-, tri-, or tetra-nucleotide repeats or alternatively cross-classified into categories of motif-complexity (simple or compound vs. pure or interrupted by nonmotif nucleotides; following Chambers & MacAvoy 2000, with compound and complex motifs combined).

Cross-species Amplifications

For cross-species comparison, we obtained DNA from five or six individuals of three other Asian species and the American species of *Crassostrea*, as described by Li et al. (2003). For each of 86 markers, PCR amplifications were done simultaneously for the five species, using a single PCR reaction mix, followed by a single acrylamide gel separation and fluorescent scan. PCR product was quantified by peak optical density per pixel (OD) in bands of similar size and appearance as bands observed in *C. gigas* on the same gel, using FMBIO software (Hitachi Genetic Systems). Owing to variable DNA template concentrations and a significant positive regression, within *C. gigas*, of OD on initial DNA concentration ($F_{1,1135} = 9.95$, $P = 0.0017$), we used a natural log transformation, $adjOD = \ln[(OD + 10)/C]$, where C is template DNA concentration. Regression of $adjOD$, on C was not significant ($F_{1,1135} = 1.02$, $P = 0.31$).

Variation in $adjOD$ was analyzed with linear models (GLM procedure of SAS version 7, SAS Institute, Inc., Cary, NC) of completely randomized block design, with 5 species × 3 repeat-motif or 4 cross-classified categories of motif-complexity × 2 different observers working with different DNA extractions (blocks). There were 3051 observations in these ANOVAs for repeat motif and 2593 observations for motif-complexity categories. Significance of block and main effects was tested by the within-block variance of species-motif combinations, using Type III sums of squares. Relationship between null-allele counts within *C. gigas* and ability to amplify markers from congeneric species was determined by stepwise regression, with $adjOD$ dependent on species and null-allele count.

Allelic diversity per locus was estimated by counting the number of unique bands (n_a) observed per marker, per species (over all markers and individuals, $n = 380$). Six 7 × 6 F₃ hybrid individuals were included in this analysis as an additional comparison. Analysis of these data must account for varying numbers of individuals successfully amplified, per species and PCR reaction (n_r), and an expected, positive correlation between n_a and n_r . The number of individuals amplified was used as a covariate in a 2-factor ANCOVA of species and repeat motif (6 × 3). Least-squares estimates of the n_a for each species, adjusted to a constant $n_r = 5$, were obtained with estimate statements in PROC GLM.

A qualitative and partially subjective assessment was made of whether each marker worked sufficiently well in another species to advise its use as a genetic marker for that species. A marker was judged likely to work for another species if it amplified from at least four of the five or six individuals surveyed and it produced bands of sufficient strength for genotypes to be reliably determined. These assessments are listed under the "cross species"

RESULTS

Heterozygosity and Null-allele Frequencies

The 96 microsatellite markers used for determination of polymorphism in *C. gigas* comprise 58 di-, 22 tri- and 16 tetra-nucleotide repeat-motif. Alternatively they can be classified into 4 crossed categories of motif-complexity: 41 are simple-pure, 23, simple-interrupted, 11, compound-pure and 21, compound-interrupted (Table 2). Interrupted repeat arrays comprise 45.8% (44/96) of the loci tested. These markers vary widely in degree of polymorphism, with numbers of alleles (n_a), ranging from 2 to 10 (mean, 5.77 ± 0.14) and observed heterozygosity (H_o), ranging from 0.125 to 1.0 (mean, 0.748 ± 0.047 ; see Table 2). Neither measure of polymorphism, however, varies significantly by repeat-motif (di-, tri-, and tetra-nucleotide motifs: for n_a , $F_{2,93} = 0.90$, $P = 0.41$ and for H_o , $F_{2,93} = 0.81$, $P = 0.45$) or motif-complexity category (simple-pure, compound-pure, simple-interrupted, compound-interrupted: for n_a , $F_{2,93} = 1.77$, $P = 0.16$, and for H_o , $F_{2,93} = 1.33$, $P = 0.27$) in our sample of F_1 hybrids.

Non-amplifying PCR-null alleles are found at 49 (51%) of the 96 loci. Minimum counts of independent PCR-null alleles per locus, in the F_1 grandparents or great grandparents of the mapping families, range from 0 to 4 and sum, over all loci, to 75 (Fig. 1). The average number of independent alleles per locus is 8.6, and the average frequency of null alleles is 0.093. Neither null-allele frequency nor null-allele count (see Table 2) varies among repeat-motifs ($F_{2,93} = 1.53$, $P = 0.22$) or motif-complexity categories ($F_{3,92} = 0.83$, $P = 0.48$).

Cross-species Amplifications

Among 86 markers tested on congeneric species, 83 (96.5%) are likely to be useful for *C. angulata*, 71 (82.6%) for *C. sikamea*, 31 (36.0%) for *C. ariakensis*, and only 11 (12.8%) for *C. virginica*. These qualitative observations of amplification are supported by a

TABLE 2.

Observed heterozygosity, numbers of alleles, and numbers of independent null alleles, by (A) repeat motif and (B) motif-complexity categories, for 96 microsatellite markers in *C. gigas*.

A. Repeat number

Motif (number of loci)	H_o , \pm SE	n_a , \pm SE	#null \pm SE
Di-nucleotide (58)	0.769 \pm 0.028	5.93 \pm 0.26	0.948 \pm 0.128
Tri-nucleotide (22)	0.704 \pm 0.046	5.27 \pm 0.42	0.545 \pm 0.207
Tetra-nucleotide (16)	0.729 \pm 0.054	5.88 \pm 0.50	0.688 \pm 0.243
Overall (96)	0.748 \pm 0.022	5.77 \pm 0.20	0.812 \pm 0.100

B. Motif complexity

Simple, pure (41)	0.742 \pm 0.033	5.54 \pm 0.31	0.683 \pm 0.153
Compound, pure (11)	0.758 \pm 0.064	6.54 \pm 0.59	1.182 \pm 0.295
Simple, interrupted (23)	0.689 \pm 0.045	5.30 \pm 0.41	0.783 \pm 0.204
Compound, interrupted (21)	0.817 \pm 0.047	6.33 \pm 0.43	0.905 \pm 0.214
Overall (96)	0.748 \pm 0.022	5.77 \pm 0.20	0.812 \pm 0.100

Figure 1. Distribution of 96 microsatellite markers, according to the number of potentially independent null alleles in 4 lineages of Pacific oysters. Forty-nine markers (51%) have at least 1 null allele, and the total number of potentially independent null alleles is 75.

quantitative analysis of PCR yields. Variance in amount of PCR product, as measured by peak optical density, is corrected for differences in initial concentration of template DNA (adjusted OD). Variance in *adjOD* is analyzed by 2-way, randomized, complete-block linear models with fixed effects. Both models are highly significant, the first accounting for 41.2% of variance in adjusted OD and the second accounting for 41.3% of variance. In both models, the block effect (different observers working with different DNA extractions) is nonsignificant. Species, on the other hand, has a highly significant effect on adjusted OD in both analyses ($F_{4,14} = 81.71$, $P < 0.0001$, for the repeat-motif analysis, and $F_{3,19} = 36.13$, $P < 0.0001$, for the motif-complexity analysis). Repeat-motif has only a mildly significant effect on adjusted OD ($F_{2,14} = 3.99$, $P < 0.043$), motif-complexity has no effect on adjusted OD, and species-by-motif interaction terms are nonsignificant. Mean adjusted OD declines from 12.6 in the focal species, *C. gigas*, and 12.4 in its nearest relative, *C. angulata*, which are not significantly different, to 10.9, 8.1, and 6.7 in the nonfocal species *C. sikamea*, *C. ariakensis*, and *C. virginica*, which are significantly different from *C. gigas* and *C. angulata* and from each other (Fig. 2).

Regression of adjusted OD on species and null-allele count per locus (#null) in *C. gigas* is significant for both variables. Species explains 35% of variance in the adjusted OD, whereas null-allele count per locus, though significant, accounts for only 0.3% of variance ($adjOD = 14.772 - [1.481 \cdot species] - [0.210 \cdot \#null]$; $F_{1,3012} = 1647.6$ for species, $P < 0.0001$ and $F_{1,3012} = 13.04$, $P < 0.0003$ for #null).

Variance in allelic diversity is analyzed with 2-way linear models, in which the main effects are species (six, including an F_3 hybrid group of *C. gigas*) and either repeat-motif or motif-complexity categories. The dependent variable, n_a , is standardized by the covariate n_i , the number of individuals amplified. Both models are significant, accounting for 43.8% of variance in the analysis of species and repeat motifs and 41.6% in the analysis of species and motif-complexity categories. In both models, the covariate is highly significant ($F_{1,394} = 61.4$, $P < 0.0001$, and $F_{1,388} = 43.74$, $P < 0.0001$, respectively) and positively related to allelic diversity (slopes of 0.43 and 0.37, respectively), as expected. Spe-

Figure 2. Average adjusted optical density (least-squares means and standard errors) of amplified microsatellite DNA markers with di-, tri-, and tetra-nucleotide repeat-motifs, among 5 species of *Crassostrea*, *C. gigas* (*Cgi*, $n = 1137$), *C. angulata* (*Can*, $n = 516$), *C. sikamea* (*Csi*, $n = 430$), *C. ariakensis* (*Car*, $n = 484$), and *C. virginica* (*Cvi*, $n = 484$). Superscripts on species names indicate significant differences; bars give the upper 95% confidence limits on least-squares means. diN, di-nucleotide repeat; triN, trinucleotide repeat; tetN, tetra-nucleotide repeat.

cies is also highly significant in both models ($F_{5, 394} = 16.08$, $P < 0.0001$, and $F_{5, 388} = 17.43$, $P < 0.0001$, respectively). Repeat-motif is significant ($F_{2, 394} = 4.21$, $P = 0.016$), whereas motif complexity is barely significant ($F_{3, 388} = 2.78$, $P = 0.041$). The interaction terms are not significant in these analyses. Mean number of alleles, adjusted to a common sample size of 5 individuals, declines from 4.54 and 4.58 in the *C. gigas* and *C. angulata* (not significantly different), to 3.42, 2.64, and 2.09 in *C. sikamea*, *C. ariakensis*, and *C. virginica*, respectively (Fig. 3). The $7 \times 6 F_3$ hybrid *C. gigas* have 4.27 alleles on average, fewer but not significantly fewer than noninbred *C. gigas* or *C. angulata*. Mean n_a for trinucleotides, 3.13, is significantly less than the mean

Figure 3. Mean number of alleles, standardized to 5 individuals, for microsatellite DNA markers, amplified from 5 species of *Crassostrea* and an F_3 hybrid group of *C. gigas* (*Cgi-In*): *C. gigas* (*Cgi*, $n = 85$; *Cgi-In*, $n = 52$), *C. angulata* (*Can*, $n = 85$), *C. sikamea* (*Csi*, $n = 78$), *C. ariakensis* (*Car*, $n = 50$), and *C. virginica* (*Cvi*, $n = 30$). Superscripts on species names show significant differences. Bars show 95% confidence intervals on least-squares means.

for tetra-nucleotide repeats (3.85) or di-nucleotide repeats (3.51), respectively.

DISCUSSION

Polymorphism in *C. gigas*

The diversity of repeat motif and motif-complexity of markers used in this study should help reduce bias in polymorphism or distribution across the oyster genome (Tóth et al. 2000, Katti et al. 2001). Interruptive mutations, which occur in almost half of the microsatellite loci in *C. gigas* (see Table 2), are hypothesized to be the first step in the "death" of microsatellites because they prevent slipped-strand mispairing and stabilize the repeat (Taylor et al. 1999). This scenario is not supported here, because neither heterozygosity nor number of alleles per locus varies among repeat-motif or motif-complexity categories. However, the power of this test is uncertain, because we measure heterozygosity and allele diversity in only four pairs of sibling F_1 hybrids. Nevertheless, we do compare a large number of loci in each repeat-motif category. Ideally, one would like to base comparisons of polymorphism among microsatellite motifs on large samples from natural populations, but the widespread occurrence of null alleles confounds estimation of heterozygosity and allelic diversity in natural populations.

Null Alleles at Microsatellite DNA Markers

Null alleles at allozyme loci have been detected in experimental crosses of several bivalve species (see references in Gaffney 1994). Gaffney (1994) reported null alleles at 10 of 11 allozyme loci in the coot clam *Mulinia lateralis*, with an average frequency per locus of 0.04. Since the advent of PCR, nonamplifying null alleles at DNA markers have been reported in the American oyster, the Pacific oyster, and the geoduck clam (Hu & Foltz 1996, Launey & Hedgecock 1999, 2001, McGoldrick et al. 2000, Vadopalas & Bentzen, 2000, Reece et al. 2001). Among 47 family tests of Mendelian transmission of microsatellites in Pacific oyster families, 17% of parental alleles were nonamplifying (McGoldrick et al. 2000). Similarly, of 94 segregation ratios tested in seven families by Launey & Hedgecock (2001), 15 showed unexpected progeny phenotypes that were best explained by null alleles. More recently, Sekino et al. (2003) report population data for nine microsatellite DNA markers in the Pacific oyster; of eight loci that are polymorphic, four show a deficiency of heterozygotes that is significant at the nominal 5% level. The mean frequency of null alleles at these four loci is 0.111.

Of 96 microsatellite DNA markers assayed in this study, 49 (51%) have at least one nonamplifying null allele in the three families examined (see Fig. 1). This is especially surprising, because these families were derived from the same natural population from which the microsatellite libraries were originally cloned. The average frequency of null alleles for oyster microsatellite loci, 0.093, is twice as high as the frequency of allozyme null alleles. If we make the simple assumption that each PCR-null allele is caused by a single nucleotide polymorphism (SNP) in a primer-binding site, then, given 3997 nucleotide base pairs in the PCR primers for 96 loci, we infer a SNP density of $49/3997 = 0.0123$, one SNP every 82 base pairs. This is likely to be an underestimate, because not all nucleotides in primer binding sites are essential to primer binding. An estimate based on the assumption that the 75 null alleles in independent lineages are different, 0.0188, is signifi-

cantly greater, but this may be an overestimate if many of the nulls segregating among inbred lines are allelic. The frequency of non-amplifying null alleles at microsatellite DNA loci in this oyster population suggests high nucleotide polymorphism in *C. gigas*.

In population studies, PCR-null alleles produce an excess of homozygotes relative to Hardy-Weinberg (random mating) equilibrium genotypic proportions. Although PCR-null alleles may be visualized by redesigning primers to more conservative parts of the flanking region (Jones et al. 1998), primer redesign does not guarantee that all PCR-null alleles will be eliminated from all populations of potential interest. It will be necessary to exercise caution in applying microsatellite markers to studies of natural bivalve populations.

Decline in Cross-species Amplification of Microsatellite Markers

The congeneric species used in this study are thought to have diverged from the Pacific oyster from <1 to >5 million years ago (Mya). Divergence times, however, must be inferred largely from molecular differences, without benefit of a fossil record or other means for calibrating rates of molecular evolution.

The Portuguese oyster *C. angulata* is the closest relative of the focal species *C. gigas*. Indeed, the Portuguese oyster is believed to be synonymous with the Pacific oyster, based on similarity of allozymes, indistinguishable larval and adult shells, complete cross-fertility, and normal meiosis in hybrids (see Boudry et al. 1998, Ó Foighil et al. 1998, and references therein). Mitochondrial DNA analysis implicates Taiwan as the source of introduction of this oyster to Portugal, likely by 16th century Portuguese traders (Boudry et al. 1998). An average 2.3% difference in mitochondrial cytochrome oxidase I (COI) nucleotide sequence suggests, however, that the Taiwanese and Japanese populations of this species may have diverged several hundred thousand years ago (Ó Foighil et al. 1998). The next closest relative of *C. gigas* is the Kumamoto oyster *C. sikamea*, which diverged perhaps 1.4–1.8 Mya, based on mitochondrial 16S rDNA sequences and allozymes (Banks et al. 1994). This divergence may also be estimated as ~2.3 Mya, based on the 9.3% average nucleotide difference for the COI sequences determined by Ó Foighil et al. (1998) and assuming a 2% per million years rate of evolution. In the same manner, an average of 14.5% nucleotide difference between the COI sequences of *C. gigas* and *C. ariakensis* suggests a divergence of ~3.6 Mya, whereas the separation of the American oyster *C. virginica* from the Asian *Crassostrea* clade (*C. gigas*, *C. ariakensis*, and *C. belcheri*) might have occurred more than 5 Mya. The latter seems to be an underestimate based on Littlewood's (1994) finding that sequences for 28S rDNA suggest that *C. virginica* is a sister group, along with *Saccostrea commercialis*, to the Asian *Crassostrea* clade.

Thus, ability to amplify microsatellite markers developed for the Pacific oyster from the DNA of congeneric *Crassostrea* species declines precipitously over an evolutionary time span of only 5–10 million years (see Fig. 2). Fewer than one out of eight Pacific oyster microsatellite markers are likely to be useful for the American oyster. Of course, we may have underestimated PCR success in nonfocal species because of 3 limitations in the survey. First, only a single PCR reaction and gel was run for each primer set, though on multiple individuals and always with the same *C. gigas* controls. Second, comparisons were performed under the PCR condition optimized for the focal species. Third, homology of PCR products across congeneric species was assumed for fragments in

the same size range as those observed in *C. gigas*, without being confirmed by sequencing. Despite these limitations, we observe a clear signal of PCR decay, perhaps owing to the large number of comparisons, 86 markers, and more than 3000 observations.

The slight but highly significant, negative correlation between null-allele frequency within *C. gigas* and PCR product yield from closely related species implies that failure of cross-species amplification results from evolution of flanking sequences. Fixation of nucleotide substitutions and insertions/deletions causes widespread PCR-null alleles within *C. gigas*, and this same process, over evolutionary time scales, results in loss of ability to amplify homologous loci from related species.

Decline in the ability to amplify Pacific oyster microsatellites from congeneric species is paralleled by a decline in allelic diversity for those markers that do amplify (Fig. 3). The validity of this trend is supported by the observation that an F₃ hybrid family of Pacific oysters has fewer alleles than the various F₁ hybrid or first generation inbred Pacific oysters or the unrelated individuals of *C. angulata* surveyed. The decline in allelic diversity across the congeneric species surveyed is consistent with ascertainment bias, the expectation that, owing to a relationship between allele size and polymorphism, loci selected to be polymorphic in a focal species are likely to be less polymorphic in other species (Ellegren et al. 1995; Goldstein & Pollock 1997). For the limited data in Table 1 of Li et al. (2003), allele size seems to be uncorrelated with either heterozygosity or allele-diversity, leaving the cause of ascertainment bias uncertain.

Homologous microsatellite loci have been successfully amplified with the same PCR primers from very divergent animal taxa—humans and chimpanzees (4–6 Mya), cow and goat (14–17 Mya), cetaceans (35–40 Mya), marine and freshwater turtles (300 Mya), and fish (470 Mya), (Schlötterer et al. 1991; Garza et al. 1995; Pépin et al. 1995; FitzSimmons et al. 1995; Rico et al. 1996). These studies suggest that microsatellite flanking regions are well conserved in vertebrate taxa, at least in selected cases.

Studies of cross-specific amplification of microsatellites in *Drosophila* provide invertebrate comparisons. Again, many studies have selected markers that could be amplified in related *Drosophila* species to reconstruct phylogenies (e.g., Noor et al. 2001, Noor M. personal communication). Two studies, however, seem to have tested cross-specific amplifications for a large, randomly selected set of microsatellite loci. Colson et al. (1999) report that 86 (80.4%) of 107 microsatellite loci characterized from *D. melanogaster* can be amplified from *D. simulans* and *D. sechellia*. Based on the nucleotide divergence of *Adh* sequences and a rate of evolution calibrated for Hawaiian species, which are endemic to islands of known age, the latter two species are estimated to have diverged from the focal species about 2.3 ± 0.65 Mya (Russo et al. 1995). These authors point out that this estimate has large standard errors and may not be inconsistent with previous estimates of 2–5 Mya. The results of Colson et al. (1999) are thus comparable with the 82.6% amplification success of *C. gigas* microsatellites from *C. sikamea*, which are believed to have diverged ~2 Mya. However, in a study of the *Drosophila virilis* group, Huttunen & Schlötterer (2002) report that, of 42 microsatellite markers developed from *Drosophila virilis*, 34 (81%) and 32 (76%) can be amplified from *D. montana* and *D. flavomontana*, respectively. Based, again, on divergence of *Adh* sequences and the Hawaiian calibration of evolutionary rate, Nurminsky et al. (1996) estimate that the *virilis* and *montana* clades diverged 9.0 ± 0.07 Mya. The success of cross-specific amplification in the *virilis* group is

clearly much higher than what we observe for the *C. gigas* versus *C. ariakensis* (36.0%) or *C. gigas* versus *C. virginica* (12.8%) comparisons. Compared with vertebrates or *Drosophila*, then, cross-specific amplification of Pacific oyster, microsatellite DNA markers show an unusually precipitous decline across a series of closely to progressively more distantly related species.

Nucleotide Diversity and High Fecundity

The evidence for high nucleotide polymorphism in the Pacific oyster is interesting in light of recent experimental evidence for a high mutational load in this species (Launey & Hedgecock 2001, Bucklin 2002). High mutational load, nucleotide diversity, and rapid sequence evolution may all be by-products of sexual reproduction in highly fecund organisms having very high rates of mortality in early life stages (Williams 1975). Female Pacific oysters routinely spawn tens of millions of eggs per year, with an upper limit of about 100 million per year (Galtsoff 1964). Species with very high fecundity likely generate more mutations than low fecundity species, owing to the large number of cell divisions required to produce millions or billions of gametes (cf. similar to the argument for male-driven evolution in humans, Li et al. 2002). An association of high mutation rate with high fecundity was previously proposed to explain the distribution of mitochondrial DNA variant haplotypes in the Pacific oyster (Beckenbach 1994). An extremely variable position of *C. virginica* in a bivalve phylogeny based on 18S rDNA was also attributed to a high substitution rate of this species (Steiner & Muller 1996). Whether the mutation rate per-cell-division, as well as the number of cell divisions, is higher in oysters than in low-fecundity species is so far unknown. The high rate of somatic cell aneuploidy in bivalve molluscs, which

correlates with reduced individual growth and probably fitness in the Pacific oyster (Leitão et al. 2001), suggests that important cellular and molecular mechanisms may be more labile in these animals than in vertebrates.

CONCLUSION

The evidence obtained from developing and mapping microsatellite DNA markers suggests that nucleotide sequences in the Pacific oyster are mutating and diverging rapidly. This nucleotide diversity has a dramatic impact on the population genetics and evolution of microsatellite markers. Nucleotide substitutions and insertions/deletions in microsatellite flanking regions produce a high frequency of null-alleles, even within the source population from which microsatellites were cloned, and contribute to failure in amplification of microsatellite markers from closely related, congeneric species. As a result, microsatellite loci should probably be identified *de novo* for each new species and validated with progeny testing before use in population analyses. Homology of microsatellite loci among related species should be confirmed by sequencing before use in phylogenetic analysis.

ACKNOWLEDGMENTS

We dedicate this manuscript to the memory of our friend and colleague, Will Borgeson, who reared and cared for oyster stocks used in this study. The authors thank Drs. P. Boudry, IFREMER, La Tremblade, France, and S. K. Allen, Jr. and K. Reece, Virginia Institute of Marine Science, for providing oyster samples. This research was supported by USDA National Research Initiative Competitive Grants Program (agreement number 99-35205-8260).

A COMPARISON OF DREDGE AND PATENT TONGS FOR ESTIMATION OF OYSTER POPULATIONS

ROGER MANN,¹* MELISSA SOUTHWORTH,¹ JULIANA M. HARDING¹ AND JAMES WESSON²

¹Virginia Institute of Marine Science, College of William and Mary, Gloucester Point, VA 23062:

²Virginia Marine Resources Commission, P.O. Box 756, Newport News, VA 23607-0756

ABSTRACT Exploited oyster stocks on public grounds in Virginia waters are subject to regular surveys effected using a traditional oyster dredge and, more recently, patent tongs. Dredges provide semiquantitative data, have been used with consistency over extended periods (decades), and provide data on population trends. Surveys with patent tongs provide absolute quantification (number of individuals per unit area) of oyster stocks but are more labor intensive. Absolute quantification of dredge data is difficult in that dredges accumulate organisms as they move over the bottom, may not sample with constancy throughout a single dredge haul, and may fill before completion of the haul thereby providing biased sampling. Selectivity of dredges versus patent tongs with respect to oyster demographics has not been rigorously examined. The objective of this study is to compare demographic oyster data collected at the same sites in the same years from both gear types. Data for the study were taken from 1993 to 2001 surveys conducted in the James River, Virginia, by the Virginia Institute of Marine Science and the Virginia Marine Resources Commission wherein the same stations were sampled by both techniques. Dredge surveys give data in oysters per bushel and assume no selective retention of live oysters with respect to shell substrate by the dredge. Patent tong surveys provide data as per tong estimates of oysters by size class and shell by volume. The hydraulically operated, 1-m square tong used in VMRC/VIMS surveys is designed to sample on and below the reef surface and include elements of buried shell that are probably not well sampled by a dredge, although the sampling ensures collection of all oysters within the tong mouth. Oysters collected by both gear types were classified as small (25–75 mm) or market (>75 mm SL) for comparisons across methods. Shell volumes collected in patent tong surveys were standardized to bushel increments assuming 35.28 L of shell per bushel. The summary plots of mean values from 1993 to 2001 and 1998 to 2001 illustrate differences related to sampling gear. More shell per unit oyster (lower bushel counts) are observed in a patent tong sample. The appropriate model for attempting to fit a predictive line is open to debate, and will be influenced by patent tong penetration as determined by the degree of consolidation of the underlying substrate. The available data do not strongly support the ability to predict a relationship between dredge and patent tong population estimates at this time.

KEY WORDS: *Crassostrea virginica*, Eastern oyster, recruitment, survey methods, Chesapeake Bay

INTRODUCTION

The Chesapeake 2000 agreement (Chesapeake Bay Program, 2000) established a 10-fold increase in the Chesapeake Bay oyster population by 2010 as one of the principal goals of Bay restoration. The baseline for this goal is the population biomass that existed at the beginning of 1994, as assessed by surveys in fall 1993. A collaborative research effort between researchers in Maryland and Virginia was performed between 2000 and 2003 to develop the baseline value. Historical data in both states was collected in support of fishery management although differences existed in details of the assessment methods preventing a singular approach to stock estimation from the accumulated data sets. Dredge surveys have been used for oyster stock assessment in Virginia for over 50 years. The Virginia Institute of Marine Science (VIMS) began annual dredge surveys at a limited number of sites in Virginia's subestuaries in 1946 and this sampling program has continued through the present with recent dredge surveys conducted in collaboration with the Virginia Marine Resources Commission (VMRC) Shellfish Replenishment Program. More recently, dredge stock assessments have been supplemented by annual patent tong surveys based on a stratified random sampling design. Patent tong sampling began in the James River in 1993 and has since expanded to include the Piankatank River (1998 to present), Great Wicomico River (1998 to present), Rappahannock River (1993, 1995–1997, 1998 to present), Tangier Sound (2001 to present) and Pocomoke

Sound (2002 to present). Here we focus exclusively on data from the James River, Virginia.

Dredge data is semiquantitative. The data exist as numbers of oysters per bushel, not bushels per unit area. Patent tong data are absolute density data (numbers of oysters per unit area). Given both the extensive historical and spatial coverage of dredge assessment, the question was posed as to the possibility of developing a conversion function relating dredge to patent tong data, thus allowing hindcasting of absolute densities of oyster populations using historical dredge data sets. This, in turn would facilitate description of historical oyster populations including estimation of the 1994 baseline for the previously described 10-fold increase goal. In this note we compare oyster density estimates from both dredge and patent tong sampling for a limited suite of observations, 1993 to 2001 surveys conducted in the James River, where both sampling approaches were used on the same populations.

MATERIALS AND METHODS

Intensive sampling of the areas within the James River, Virginia that are actively fished for oysters (Fig. 1) is completed each fall as part of a collaborative program between VMRC and VIMS. Patent tong surveys use a stratified random sampling design with historical reefs (Baylor 1894, Haven et al. 1981) forming the basis of strata delineation. Individual samples were collected by a hydraulic patent tong with a one square meter sample capability. The patent tong used in VMRC/VIMS surveys is designed to sample on and below the reef surface, and include elements of buried shell

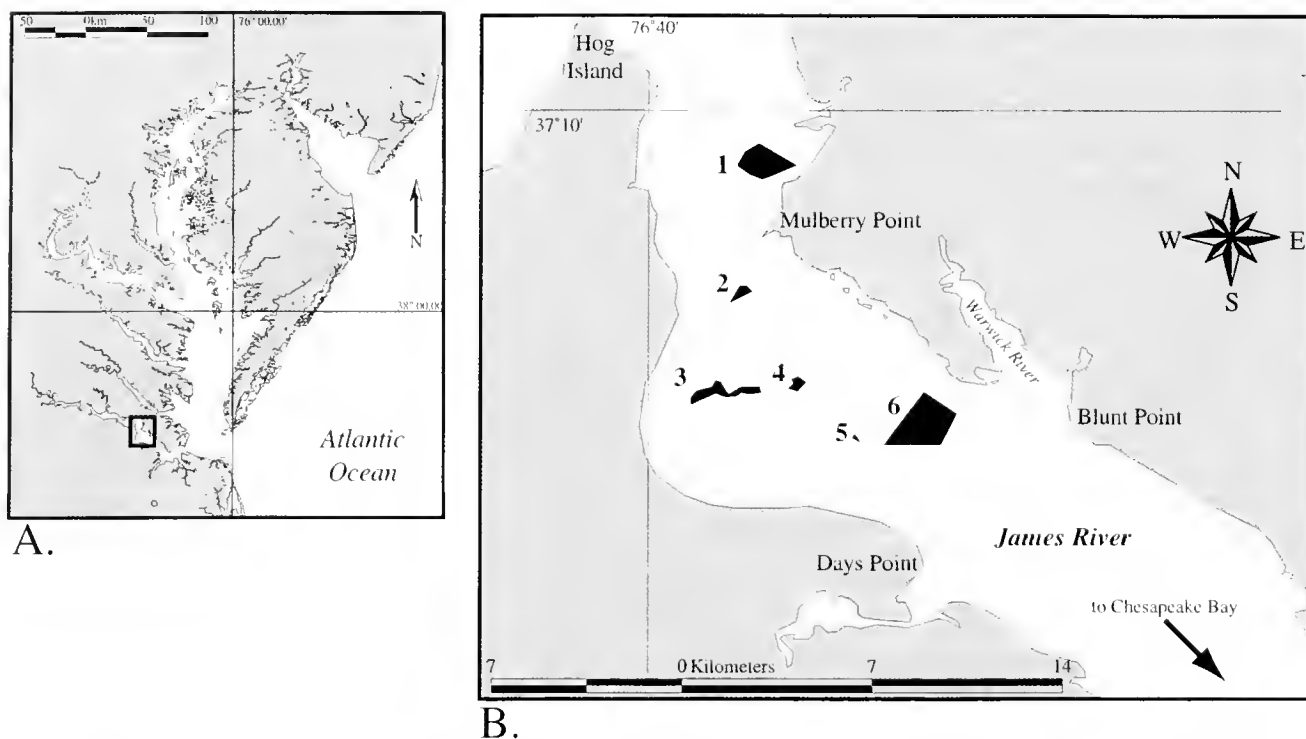

Figure 1. Map of Chesapeake Bay, USA (A) and the James River, Virginia (B) showing the reefs used for sample collection in this study: (1) Deep Water Shoal, (2) Horse Head, (3) Point of Shoals, (4) Cross Rock, (5) Dry Lumps, and (6) Wreck Shoals.

that are probably not well sampled by a dredge, although the sampling insures collection of all oysters within the tong mouth. Since 1998, all oysters collected on the patent tong survey have been measured in the field and length-frequency data have been collected at 5-mm size intervals. Prior to 1998, oysters were simply characterized as small (25–75 mm SL) and market (SL >75 mm). Total shell volume (liters) is also recorded for each patent tong grab.

In addition to patent tong sampling the exploited James River oyster stocks are subject to regular examination within surveys effected using a traditional oyster dredge (e.g., dredge mouth 1.2 m wide, 0.1 m long teeth, bag volume of 147.87 L or 4.19 bushels). Oysters from either sample type were described as 1 of 2 size classes (small, market) on the basis of length. Oyster abundances from patent tong surveys were converted to numbers of oysters using the conversion factors of 1000 oysters bushel⁻¹ for small oysters (25–75 mm SL), and 500 oysters bushel⁻¹ for oysters of marketable size (SL > 75 mm). This allows an estimation of the number of oysters bushel⁻¹, the unit given by dredge data, and for patent tong data by dividing the converted abundance values for each size class by the total shell volume bushel⁻¹ recorded at that patent tong grab site. The resulting abundance estimates (oysters of a size class bushel⁻¹) were summed within a single patent tong grab and then all of the grabs within 1 site in 1 year were averaged to provide estimates of average numbers of small, market, and total oysters bushel⁻¹ with standard errors of the mean.

Quantification of dredge data is more difficult than patent tong data in that dredges accumulate organisms as they move over the bottom, may not sample with constancy throughout a single dredge haul, and may fill before completion of the haul, thereby providing biased sampling in favor of the “early” portion of the haul. Al-

though Powell et al. (2002) describe bias against shell in oyster dredge samples, these samples were collected during 1 minute tows in which the dredge never filled. The samples described in this study were all collected by tows of longer duration where the dredge filled completely before the end of the tow. For this study we assume no selective retention of live oysters with respect to shell substrate by the dredge due to the method in which the dredge was fished. Selectivity of dredges versus patent tongs with respect to demographics has not been rigorously examined in Virginia waters, especially in shell-poor substrates where tongs dig deeply into buried shell material. Conversely, dredges provide semiquantitative data, have been used with consistency over extended periods (decades), and thus provide data on population trends. The challenge in the current objective of estimating absolute numbers of oysters is to use dredge data in a consistent quantitative approach.

RESULTS AND DISCUSSION

Within the 1993 to 2001 comparison, we have used the same stations for both dredge and patent tong surveys. Pre 1998 data may well have suffered from subjective distinction of the small versus spat categories in the field. Given the annual abundance of spat, this may have led to inconsistent distinctions of these size categories and occasional large discrepancies in the resulting plot of total oysters per bushel as estimated by dredge and patent tong methods (Figs. 2A, 2C, and 2E). Examination of the data collected at 5-mm size intervals for 1998 to 2001 is illustrated in Figures 2B, 2D, and 2F.

Recalling that both figures give points that are mean values, the plotted relationships represent a considerable body of individual

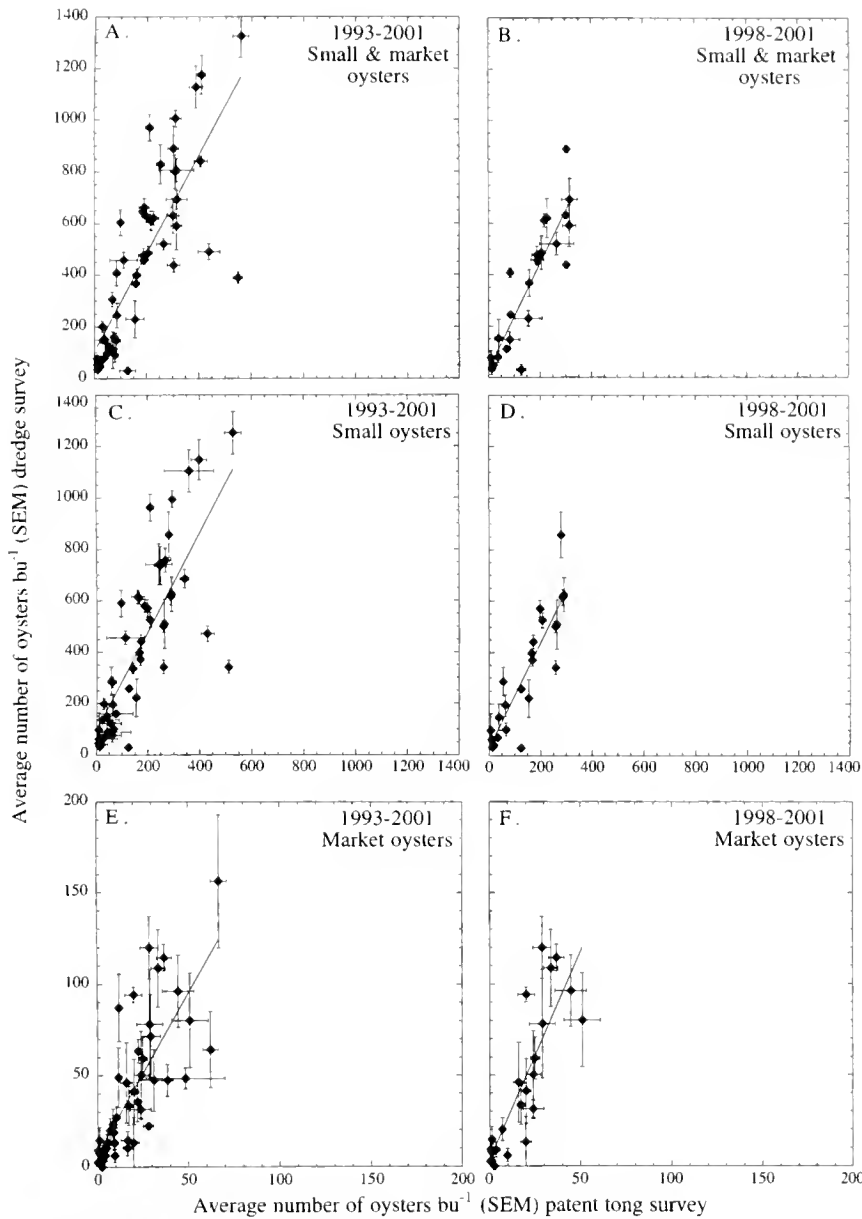

Figure 2. Average total number of oysters (A, B), small oysters (C, D), and market oysters (E, F) bu⁻¹ collected from 6 reefs in the James River with patent tongs in comparison to dredge data. Error bars indicate standard error of the mean. Note the difference in scale between plots A–D and plots E and F. (A) $y = 104.17 + 1.9x$, $R^2 = 0.65$, (B) $y = 27.46 + 2.08x$, $R^2 = 0.79$, (C) $y = 99.31 + 1.91x$, $R^2 = 0.62$, (D) $y = 27.92 + 2.05x$, $R^2 = 0.78$, (E) $y = 6.79 + 1.77x$, $R^2 = 0.62$, and (F) $y = 4.07 + 2.28x$, $R^2 = 0.70$.

data points (annual dredge survey $n > 24$, annual patent tong $n > 130$). All plots illustrate the different results obtained by tong and dredge respectively. These data show that the assumption of no selective retention of live oysters with respect to shell substrate by the dredge due to the method in which the dredge was fished is not correct. The dredge samples appear to be biased towards live oysters with an enrichment of live oysters versus cultch on the order of a factor 2. Similar patterns of dredge sample enrichment have been reported by Powell et al. (2002) for oyster dredges with 1-min tows.

Enrichment in dredge samples may occur because dredging takes the top layer of shell whereas the patent tong also includes a buried layer of shell where it occurs. So more shell per unit oyster

can be expected in a tong sample with a concomitant lower bushel count of oysters—again the historical unit of record. On the other hand, a plot of the grand means of a very large amount of data on a single plot suggests that a line might be fitted to this data. Any attempt to fit a line for predictive purposes through these data would not pass through the origin unless a nonlinear fit was used. The appropriate model for such a fit is open to debate, and may be influenced by the nature of the underlying substrate in many locations—for example oyster reefs in the productive part of the James River have a hard base into which the patent tong does not sink easily. Universal application of a fitted “predictive” relationship may, however, be tenuous. In contrast to the James River, oyster reefs in the Rappahannock River may be less consolidated

resulting in deeper penetration of the underlying substrate. Site-specific application may be more appropriate.

Clearly, annual surveys using standardized methods and sampling designs can provide a wealth of relevant stock assessment information, provided caution is used when extrapolating site-specific data beyond regions that have been surveyed. This exercise demonstrates, different methods and provide slightly different estimates of the available resources, and these estimates are strongly affected by modest changes in available substrate per unit area.

DECADAL SCALE CHANGES IN SEASONAL PATTERNS OF OYSTER RECRUITMENT IN THE VIRGINIA SUB ESTUARIES OF THE CHESAPEAKE BAY

MELISSA SOUTHWORTH* AND ROGER MANN

Virginia Institute of Marine Science, College of William and Mary, P.O. Box 1346,
Gloucester Point, Virginia 23062

ABSTRACT Reproductive periodicity of sessile estuarine invertebrates reflects local seasonality of environmental (temperature, salinity) and biologic (food) parameters. Estuaries are ephemeral features in geologic time but considered somewhat constant in the course of recent human history (decadal time scales). Analyses of long-term trends in eastern oyster (*Crassostrea virginica*) settlement periodicity since 1960 in three major Chesapeake Bay rivers (James, Piankatank and Great Wicomico Rivers) of the Chesapeake Bay show marked changes within the 4-decade time frame. The 50th percentile of cumulative recruitment occurs between day 194 and 250 of the year depending on year and location. Significant coherence in interannual variation is observed across a wide range of sites. These patterns are related to pre and post disease (both *Haplosporidium nelsoni* and *Perkinsus marinus*) events, periods characterized by high and low river flow, varying harvest pressure, and trends arguably associated with directed climate change.

KEY WORDS: eastern oyster, *Crassostrea virginica*, settlement, recruitment, climate change, Chesapeake Bay

INTRODUCTION

Sessile marine invertebrates are suitable candidates to examine long-term changes in climate and anthropogenically induced changes in local environments. Recruitment intensity and periodicity are annual signals of the integrated impact of local perturbations superimposed on long-term (geological scale) changes. Commercially valuable species have been the focus of quantitative annual monitoring programs in support of fishery management, but have been examined in a limited manner with respect to combined impacts of climate change and fishing pressure (Allen & Turner 1989, Kim & Powell 1998). Estuarine environments are particularly susceptible to stress from cyclical changes on time scales ranging from tidal to annual. Long-term data on marine invertebrate communities in estuaries are limited, especially so in regions subject to increasing watershed development, water quality degradation, habitat destruction and/or diseases, and parasites. Temperate estuaries are natural laboratories where cumulative impacts of human societal growth are highly visible. Eastern oysters, *Crassostrea virginica*, are considered sentinel organisms in estuaries on the North American Atlantic seaboard in terms of biologic and geologic (habitat) function. Their loss in such environments predicates significant changes in ecosystem function and food chain dynamics with trickle down effects on nutrient cycling, species richness and complexity, stability of food webs, and production to support commercial fisheries.

The eastern oyster has long been recognized for its ecologic and commercial importance in the Chesapeake Bay, but the species has suffered numerous insults over the past century. Over fishing of oysters in the Chesapeake Bay has long been recognized. Maryland's harvests have been in decline since about 1885 and Virginia's since about 1904 (Hargis & Haven 1995). Recent catches are less than 1% of what they were 100 years ago. In addition to the continuous removal of market and seed oysters, uncounted millions of tons of shell have been removed for use in road building, chemical processing, and poultry husbandry. This essential habitat loss has resulted in the gradual replacement of 3-dimensional intertidal reefs, with 2-dimensional, subtidal reefs that are highly susceptible to siltation and burial (Hargis & Haven 1995). The

onset of *Perkinsus marinus* in 1950 (Andrews 1996) and the arrival of the non-native disease *Haplosporidium nelsoni* (MSX) in 1959 (Burrison et al. 2000) caused further decline in the already seriously depleted oyster populations. Despite efforts of replenishment, beginning as early as 1924 in Maryland and 1928 in Virginia, oyster stocks have continuously declined. In response to these accumulating problems, monitoring efforts increased and became routine starting in the late 1940s and early 1950s in both Maryland and Virginia (Andrews 1982).

Early studies on oyster settlement (spat or young of the year oysters undergoing metamorphosis and attaching to the bottom) and recruitment (those oysters that survive post settlement to become part of the population) in Virginia focused on seasonal patterns in onset, duration, intensity, and cessation of oyster settlement (Andrews 1951, Andrews 1954). With the onset of the diseases, *P. marinus* and *H. nelsoni*, in the late 1950s and 1960s these patterns changed. Population studies from 1946 to 1967 in the James River showed that post *H. nelsoni* settlement was of lower intensity and occurred during a shorter period when compared with pre *H. nelsoni* settlement (Andrews 1982).

There have been two other long-term studies of oyster settlement and recruitment in the Virginia portion of the Chesapeake Bay. Haven and Fritz (1985) focused on the temporal and spatial distribution of oyster settlement. They examined weekly settlement in the James River from 1963 to 1980. They separated the river into three distinct settlement zones related to water circulation and found that settlement was synchronous at stations within a zone, but occurred 1 to 2 weeks earlier at stations in the upriver zones compared with the downriver zones. They also found that post *H. nelsoni* settlement intensity was lower and occurred in discrete pulses, 1 to 2 weeks in duration, instead of the continuous settlement pattern seen in pre *H. nelsoni* conditions. Austin et al. (1996) performed a time series analysis of recruitment from 1946 to 1993 in the four major sub estuaries of the Virginia portion of the Chesapeake Bay. The data used were from the Virginia Institute of Marine Science's (VIMS) annual fall dredge survey. They found a relationship between spat (young of the year, recently settled oysters) and subsequent seed at 2- and 3-years post settlement, but no relationship between recruitment numbers and spring and summer water temperatures and river discharge. Their study provided an overall picture of interannual variation in recruitment,

*Corresponding author. E-mail: melsouth@vims.edu

but did not provide any information on interannual variation in the onset and duration of oyster settlement. Whereas both of these studies provide insight into oyster settlement and recruitment in the larger rivers of the Virginia portion of the Bay, relatively little effort has been devoted to critical examination of changes in settlement patterns in some of the smaller rivers. VIMS provides a descriptive monitoring report of settlement and recruitment in both small and large rivers in Virginia (summaries available at <http://www.vims.edu/mollusc>) on an annual basis. Oyster settlement in these smaller systems and the overall health of resident oyster populations has become increasingly important over the past decade, primarily due to increasing restoration efforts in these smaller systems. The Piankatank and Great Wicomico Rivers in particular have served as important building blocks in a long-term plan for oyster restoration in Virginia (Bartol & Mann 1997, Southworth & Mann 1998).

In this study, we examine long-term changes in the Chesapeake Bay oyster population in response to the cumulative effects of the previously described stressors. We report the long-term trends in periodicity of oyster settlement in 3 rivers, namely the James, Piankatank, and Great Wicomico. These systems offer contrasting watershed drainage areas, river flows, and basin morphologies. We use duration of settlement period and mean date of settlement as indicators of environmental quality within a single year for each location. Comparisons were made within and between river systems over a 40-year period, to examine the relative roles of large-

scale climatic events, local physical functions, and biologic stressors in driving the settlement patterns.

The value of historical long-term data sets, such as the VIMS shellstring survey used in this study, is in the consistency and length of data collection. Due to this longevity, the data can provide valuable insight into long-term trends (on a decadal or longer time scale) that most experiments do not afford. However, given that the initial data collection often has a different objective (i.e., was not designed to examine long-term trends) we have adopted caution in the analysis and interpretation of the data. As such we provide an overview of oyster settlement timing based on the long-term data set in a largely descriptive manner, using statistics that are appropriate to the data set.

MATERIALS AND METHODS

The James River (Fig. 1) has a large watershed, (approximately 27,000 km², Chesapeake Bay Program; <http://www.chesapeakebay.net>) with yearly average stream flow ranging from 4,400 to 21,500 ft³/sec (United States Geological Survey data; <http://nwis.waterdata.usgs.gov>). Historically it was a major seed-producing river, with the seed area extending approximately from the Nansemond River up to Deep Water Shoal (Fig. 1), that supplied Virginia and Maryland planters with an average of 2 million bushels each year (Andrews 1982). The Piankatank and Great Wicomico Rivers (see Fig. 1) are relatively small watersheds (approximately 575 and 337

Figure 1. Map of the Chesapeake Bay showing the locations of the James, Piankatank, and Great Wicomico Rivers and the location of the 8 study sites (numbering system used throughout figures): (1) Deep Water Shoal, (2) Point of Shoal, (3) Wreck Shoal, (4) Miles Watch House, (5) Ginney Point, (6) Palace Bar, (7) Glebe Point, (8) Hudnall.

km², respectively, Chesapeake Bay Program: www.chesapeakebay.net) with a yearly average stream flow ranging from 50 to 460 ft³/sec in the Piankatank River and 57 to 266 ft³/sec in the Great Wicomico River (U.S. Geological Survey data: <http://nwis.waterdata.usgs.gov>). Both rivers have been termed trap-type estuaries by Andrews (1979) and are characterized by gyre-like circulation in their lower reaches. Historically, these rivers were used for oyster seed production and grow-out to market size on leased grounds. More recently, these rivers have become important in restoration efforts, with both rivers receiving shell plants and artificial oyster reefs (Southworth et al. 2002, Berman et al. 2002).

VIMS monitors oyster settlement annually using shellstring substrates from late May to early June through October. A shellstring consists of 12 oyster shells of similar size (standard length 276 mm.) drilled through the center and strung (inside of shell facing substrate) on heavy gauge wire (Fig. 2). Throughout the monitoring period, shellstrings were deployed approximately 0.5 m off the bottom at each station. Shellstrings were usually replaced after a 1-week exposure. The number of spat that attach to the smooth underside of the middle 10 shells during the exposure period were counted under a dissecting microscope. An estimate of the mean number of spat shell⁻¹ for the exposure period

TABLE 1.

Summary of the Virginia Institute of Marine Science oyster settlement monitoring stations in the James, Piankatank, and Great Wicomico Rivers, Virginia.

Station # (from Fig. 1)	River System	Station	Years Covered by Survey	Total Number of Years
1	James	Deep Water Shoals	64-72, 74-02	38
2	James	Point of Shoals	68-02	35
3	James	Wreck Shoal	68-02	35
4	James	Miles Watch House	63-97	35
5	Piankatank	Ginney Point	65-02	38
6	Piankatank	Palace Bar	67-02	36
7	Great Wicomico	Glebe Point	65-02	38
8	Great Wicomico	Hudnall	65-02	38

was obtained by dividing the total number of spat observed by the number of shells examined (10 shells in most cases). This estimate was then standardized on a per week basis (day 1 of the year = January 1) to allow for comparison between years and calculation of cumulative spat shell⁻¹ estimates for each year.

A total of 8 sites were selected for the study, 4 in the James River and 2 each in both the Piankatank and Great Wicomico Rivers with 34 to 38 years of data per site (Table 1). Figure 1 shows the location of the sites in their respective rivers. Sites were chosen based on their location in the river and consistency of collection of data. Data analyses were as follows. A sigmoid curve was produced for each year at each site using the formula:

$$Y = \frac{a}{1 + e^{-\frac{(x-x_0)}{b}}}$$

Where:

a = the maximum y (i.e., the total number of spat shell⁻¹ in a given year).

b = the maximum slope of the line.

X_0 = 50th percentile of cumulative recruitment (i.e., the day of the year when 50% of " a " has been obtained).

Examinations of temporal trends in X_0 were made by plotting site-specific values of X_0 for the multiyear duration of the data set. A common characteristic of time series data sets is the illustration of different features and patterns over different time scales. For example, there may be large interannual variation in a particular data set, but the overall trend on a larger decadal scale may show a steady decline. Smoothing is a tool available to identify trends within long-term data sets. One such smoothing technique, developed by Cleveland (1979), is Loess (originally LOWESS or LOcally WEighted Scatterplot Smoothing), which applies the tricube weight function to weight the data. A weighted regression is performed for each point along the smooth curve. Loess obtains each point along the smooth curve by performing a regression on the data points close to the curve point where the closest points are more heavily weighted. The user determines the amount of smoothing, which affects the number of points in the regression. This technique is robust and sufficiently well accepted to be included in most statistical packages (Cleveland 1979, 1993).

Temperature is generally considered to be an important ecological parameter influencing reproductive periodicity and larval development rates in oyster populations (Thompson et al. 1996).

We sought to examine the influence of temperature on periodicity and intensity of oyster settlement in the long-term data sets. Whereas temperature data goes back to the early 1980s for the James River and the early 1990s for the Piankatank River, consistent data for all three systems was only available from 1998 through 2002. Therefore, we limited comparisons and analysis to those 5 years. Temperature residuals were calculated by subtracting the temperature in the James River from that in the Piankatank and Great Wicomico Rivers for each day throughout the spawning season. A positive result can be interpreted as that system being warmer than the James River, whereas a negative result means the system is colder than the James River. The sum of the residuals for a particular river throughout the spawning season describes the magnitude of the difference between the river of interest and the James River.

Records of salinity over the time period examined in the three systems are also very limited; however, there are comprehensive river flow data near Richmond in the James River and near Dragon Swamp in the Piankatank River for the entire time period and in Bush Mill Creek (which flows into the Great Wicomico River) from 1963 through 1986, from the United States Geological Survey (<http://nwis.waterdata.usgs.gov>) records. Whereas river flow data does not give us a direct measure of salinity, it can be used as a measure of relative salinity in that there is an inverse relationship between river flow and salinity (Mann & Evans 1998).

RESULTS AND DISCUSSION

The relationship between day of the year and the cumulative sum of spat shell⁻¹ was accurately described using the fitted sigmoid curve (R^2 values >0.92) and an example curve from each river is shown in Figure 3. There was a wide range in X_0 over the period examined in all three rivers. Over the 40-year period there was as much as a 60 to 90 day difference in the timing of oyster settlement between years and between river systems (Fig. 4). This plot demonstrates variability in oyster settlement timing between systems and years, but fails to identify any trends that may exist in the data. Therefore the data was smoothed using Loess and the resulting curves are shown in Figure 5.

The smoothed curves still illustrate the large range in the timing of oyster settlement observed over the 40-year period. Aside from the early years (through 1970) in the James River, settlement timing between sites within the same river was similar (usually within 1 week of each other). The Great Wicomico River shows the largest variation in timing, whereas the Piankatank River was fairly consistent in terms of settlement timing, especially compared with the other two systems. Prior to the mid 1970s, settlement was consistently earlier in the Great Wicomico and Piankatank Rivers than in the James River and there was a large difference in settlement timing between the systems. Settlement in the James River tended to be late in the year with the majority of oyster settlement occurring from late August into early September. There was a trend toward earlier settlement in both the James and Great Wicomico Rivers throughout the late 1970s and 1980s. Beginning in the early 1990s settlement timing in all three systems was increasingly later in the year and has remained similar (within 3 to 4 weeks of each other) since then. In particular, oyster settlement in the James River appears to have undergone the largest change such that current settlement patterns are similar to the other two systems; however, settlement in the Great Wicomico remains about 2 weeks earlier than in the other two systems.

There are many environmental factors that have the potential to affect both the timing and magnitude of oyster settlement. Among these are single large-scale meteorologic events, which may temporarily but fundamentally alter the conditions in a system, such as tropical storms or hurricanes (Haven et al. 1974), temperature (Medcof 1939), salinity (Butler 1949), disease (Ford & Figueras 1988, Choi et al. 1989), and location of broodstock in a system (Haven & Fritz 1985). One or all of these factors may explain the variability in oyster settlement timing observed over the past 35 to 40 years in these rivers.

Throughout the duration of the study, the most significant meteorologic event to occur during a settlement season was Hurricane Agnes that entered the Chesapeake Bay in June of 1972 and resulted in record amounts of flooding in most of the major sub estuaries (Andersen et al. 1973, Schubel et al. 1974). This flooding had a major effect on oyster populations in the Bay causing 2 to 70% mortality in adult oysters (Haven et al. 1974). The mortality was mostly limited to the shallower systems and the upper bay and upriver sites. Mortality in the James River was as high as 85% at the more upriver sites, but was relatively low and similar to normal years at the more downriver sites, where the majority of the broodstock was located (Haven et al. 1974). Hurricane Agnes was responsible for almost complete recruitment failure in 1972 and severely reduced settlement in 1973 (Haven et al. 1974). Despite these short-term effects, Hurricane Agnes seems to have had little effect on the long-term trends in timing of the set in the Virginia portion of the Chesapeake Bay (Fig. 5).

Temperature and salinity affect every aspect of an oyster's biology, including gonadal development and timing of the spawn. Temperature in particular is viewed as the single most important factor controlling when the eastern oyster spawns (Shumway 1996). Figure 6 shows the daily temperature residuals for the 1998 to 2002 period for the Piankatank and Great Wicomico Rivers compared with the James River. In general, the temperature in the Great Wicomico River tends to be 1 to 2 °C warmer than the James River, whereas the temperature in the Piankatank River tends to be about 1 °C cooler than the James River. Both smaller rivers exhibit similar early season increases of 2 to 4 °C over a short (2 to 3 weeks) time period when compared with the James River. Further exploration of this temperature relationship can be examined by observing the cumulative day degrees as shown in Figure 7. The cumulative day degree is a sum of all of the temperature residuals for a particular year and system and demonstrates that the Great Wicomico River is, on average, warmer than the James River whereas the Piankatank River is, on average, cooler than the James River.

The difference in temperature between the three systems may explain several aspects of the observed settlement trends (see Fig. 5). Throughout the observed time span, spawning in the Great Wicomico tended to occur 1 to 2 weeks earlier than in the other two systems. Whereas both the Piankatank and the Great Wicomico Rivers showed a pronounced increase in temperature early in the season when compared with the James River (see Fig. 6), the Great Wicomico River also was on average several degrees warmer than the other two systems. Several studies have found that the rate of temperature change can be as important in inducing spawning in oysters as some "critical" level being obtained (Medcof 1939, Butler 1949). If we assume the temperature residuals in these systems have remained relatively consistent over the past 40 years then the increase in temperature observed in the Great Wicomico River early in the season combined with the overall

Figure 3. Examples (from 1991) of the sigmoidal curve fit of day of the year versus cumulative sum of spat shell⁻¹ from Deep Water Shoal (#1) in the James River (top), Palace Bar (#6) in the Piankatank River (middle) and Glebe Point (#7) in the Great Wicomico River (bottom). Note the difference in y-axis scales between panels.

higher temperatures obtained throughout the spawning season may explain the earlier settlement observed in that system. The Piankatank River seems to warm at a similar rate to the Great Wicomico early in the spawning season, but may take longer to reach that "critical" temperature necessary to induce spawning.

Salinity, while not as important as temperature in determining the timing of spawning, can still affect gametogenesis, especially in flood conditions. Butler (1949) found that gametogenesis was

delayed in salinities less than 6 ppt. Laboratory examination of gonads from field collected animals from May to August showed a 2-month lag in gametogenic development in about 90% of the oysters from a low salinity site (0–6 ppt) when compared with a high salinity site (6–15 ppt; Butler 1949). Whereas a few oysters did undergo normal gametogenesis and spawn at low salinity, the majority of them failed to produce gametes until salinity rose above 8 ppt (Butler 1949).

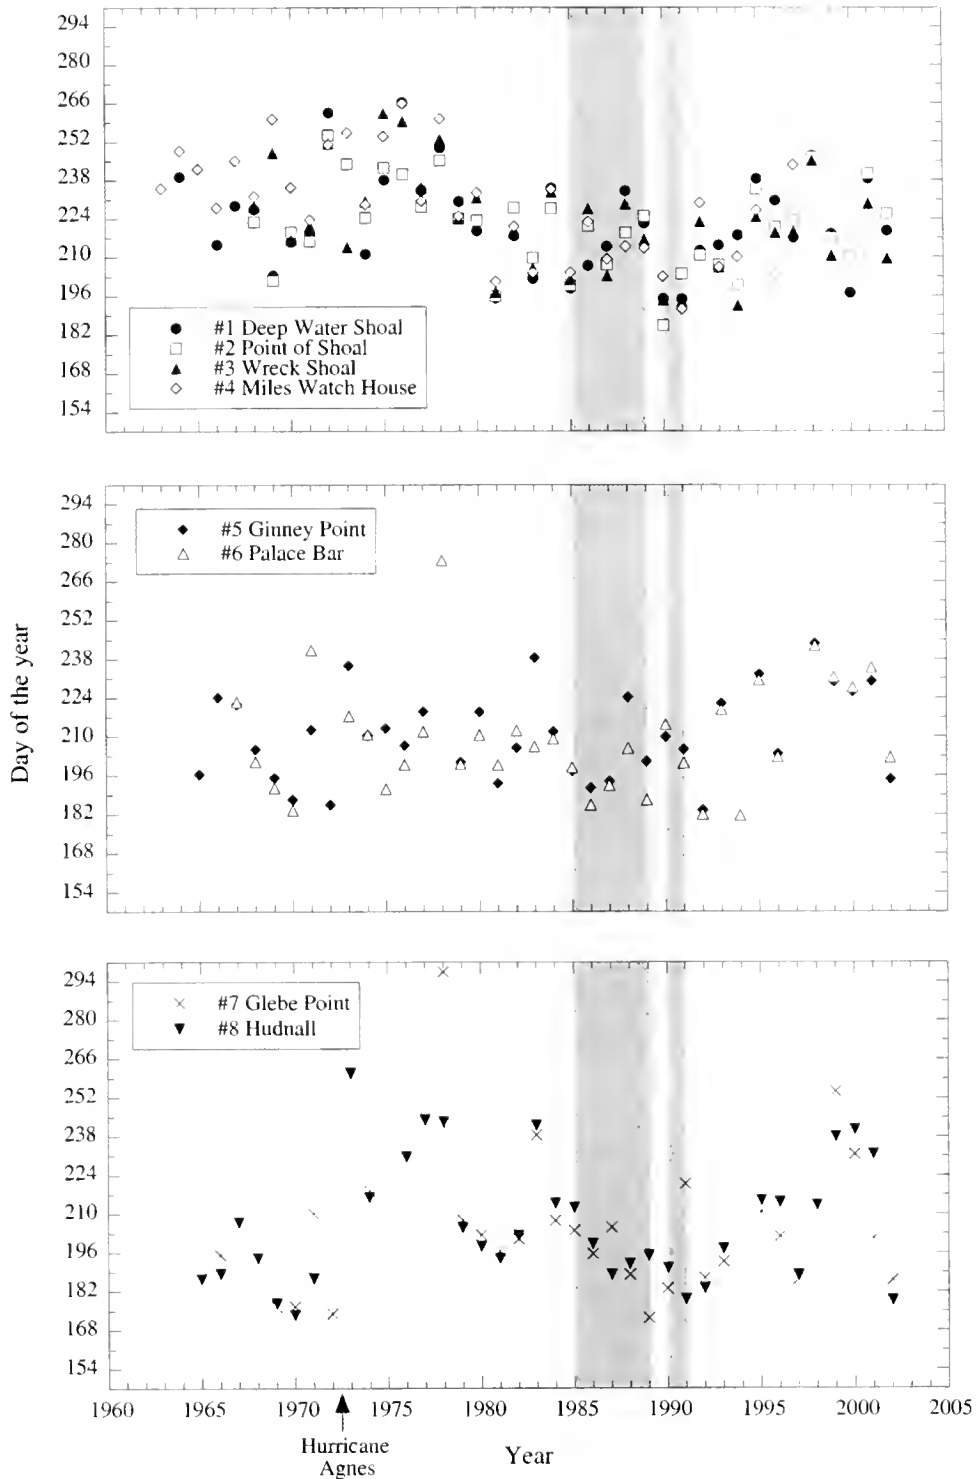

Figure 4. Plot of X_{50} (day of the year when 50% of the total settlement has occurred) over the 40-y study for the James (top), Piankatak (middle) and Great Wicomico (bottom) Rivers. Station numbers correspond with Figure 1 and Table 1. Shaded regions represent dry years as discussed in text.

River flow has been shown to have an inverse relationship with salinity (Mann & Evans 1998). Figures 8, 9, and 10 show average monthly water flow residuals (difference from the long-term average) from USGS records for May through September from 1960 through 2002 in the James and Piankatak Rivers and from 1964 through 1986 in the Great Wicomico River respectively. The water

stations where data was obtained for each system drain approximately 65%, 45%, and 5% of the total watershed of the James, Piankatak and Great Wicomico Rivers, respectively. Applying corrections to the reported raw data for watershed area and the percentage of watershed reflected in the raw data we note that the run-off in the Piankatak and Great Wicomico Rivers are in the

Figure 5. Cumulative recruitment (X_0) data for the James (top), Piankatank (middle) and Great Wicomico (bottom) Rivers, smoothed with the Loess technique in relation to year. Station numbers correspond with Figure 1 and Table 1. Shaded regions represent dry years as discussed in text.

10s to 100s of cubic feet sec^{-1} whereas the James is in the 1,000s to 10,000s cubic ft sec^{-1} , at least two orders of magnitude higher. All three systems were characterized by low flow during the 1960s. Hurricane Agnes (June, 1972) appeared to have disproportionate impact in the James River compared with the other two systems. During the 7-year period from 1985 through 1991, only 1989 was considered a wet year for the Chesapeake Bay as a whole (Burrison & Ragone Calvo 1996). The 1985 to 1991 drought was more apparent in the James River where 5 of the 7 years had a net flow lower than average whereas only 3 out of the 7 years showed a net flow lower than average in the Piankatank River. Further examination of the relationship between oyster settlement and year (see Fig. 5) for the drought conditions of the late 1980s and early

1990s shows that the oysters spawned earlier in the year than during wetter years.

Salinity can have an indirect effect on oyster spawning through its influence on oyster diseases. Two oyster pathogens, *Haplosporidium nelsoni* and *Perkinsus marinus* were present in varying intensities in all three systems throughout the 40-year time frame of the study. Both diseases have been shown to have a detrimental effect on development of the gonad, especially in heavily infected animals (Choi et al. 1989, Ford & Figureas 1988). Therefore we examined the option that the heavier the infection, the greater effect that infection would have on the animals. The distribution and abundance of both diseases is primarily controlled by salinity (Burrison & Andrews 1988). *H. nelsoni* requires a salinity of

Figure 6. Daily average temperature differences (residuals) in the Piankatank and Great Wicomico Rivers as compared with the James River over the course of the annual spawning season; averaged from 1998 to 2002 when detailed water data was available for all 3 systems. Station numbers correspond with Figure 1 and Table 1.

approximately 15 ppt to infect oysters and is expelled in spring if salinities remain less than 10 ppt for more than 10 days (Andrews 1988). *P. marinus* requires salinities of approximately 12 ppt and can persist for several years at low seasonal salinities without causing substantial mortalities (Burrison & Andrews 1988). Thus *H. nelsoni* only moves into the upper bay and the upper reaches of the sub estuaries during drought conditions. *P. marinus* showed similar distributions to *H. nelsoni* until drought conditions persisted for the 7-year period in the late 1980s and early 1990s (see Figs 1 and 2 in: Burrison & Ragone Calvo 1996). Since that time *P. marinus* has persisted in the upper James River and throughout the Piankatank and Great Wicomico Rivers even though salinities returned to normal (compared with the long-term means) during the mid to late 1990s.

The effect that the two diseases have on oyster spawning, especially that of *P. marinus*, may explain the observed changes in settlement timing in the James River during the late 1980s. As disease became more prevalent throughout the James River, the difference in settlement timing between the most upriver (Deep Water Shoals) and downriver (Miles Watch House) stations decreased (see Fig. 5). The observed differences between the 3 rivers have also decreased as disease prevalence has increased.

The change in settlement timing in the James River may be related to the location of the broodstock oysters in that system and how that location has changed over the study period. It has been suggested that, historically, the majority of the settlement on the

upper seed river area (upriver of Wreck Shoal, see Fig. 1) originated from the oysters located in the lower, more saline, part of the river (Haven & Fritz 1985). With the onset of *H. nelsoni* in 1959 many of the oysters in the lower part of the river were killed. Further excursions of both diseases into the upper reaches of the James, throughout the seed area and especially that observed over the past fifteen years, has led to further decline of the downriver broodstock populations. Data from the annual VIMS fall dredge survey (<http://www.vims.edu/mollusc>) show that the percentage of broodstock upriver of Wreck Shoal (Fig. 1 for location in river) has been steadily increasing, whereas the broodstock downriver of Wreck Shoal has been decreasing (Fig. 11). We suggest that, historically, the oysters in the upper seed area provided the first smaller settlement pulse, whereas the more downriver oysters provided the larvae for the major settlement events that typically occurred in late August and early September. With the decline of these downriver populations, the majority of the settlement event increasingly originates from the upper seed area, with an accompanying earlier settlement peak.

In summary, the trends in oyster settlement timing observed over the past 40 years in the James River can be attributed to several interacting factors. There are anthropogenic inputs in the form of watershed influences and over harvesting that have been occurring in the river for the past century (Hargis & Haven 1995) and, despite continuing depleting stocks, some harvesting still occurs in the system (James Wesson, Virginia Marine Resources

Figure 7. Cumulative day degrees for the Piankatank and Great Wicomico Rivers using the James River as the zero mark for the period 1998 to 2002 when detailed water data was available for all 3 systems. Station numbers correspond with Figure 1 and Table 1.

Commission, Newport News, VA 23607; personal communication). With the added insult of the 2 disease species, *H. nelsoni* and *P. marinus* and the subsequent change in location of the brood-stock populations, the present distribution of oysters in the James River is very different from what was observed several decades ago. Overall there has been very little change in the timing of oyster settlement in the Piankatank River, especially compared with the changes observed in the James and Great Wicomico Rivers. Unlike the James River, there are very few anthropogenic influences in the Piankatank River, there has been no commercial

harvesting in the system for decades (James Wesson; personal communication) and there are few watershed influences. The small change in settlement timing that we observed in the late 1980s and early 1990s are most likely associated with the drought of the late 1980s when *P. marinus* infections moved into the upper portion of the estuary (Burreson & Ragono Calvo 1996). Throughout the duration of the study, the Great Wicomico has exhibited the largest interannual variation in settlement timing. The drought of the late 1980s did not really alter the location of disease-infected oysters (Burreson & Ragono Calvo 1996), and given the small size and

Figure 10. Average monthly stream flow residuals (monthly average minus long-term average) from May through September from USGS records for the Great Wicomico River from 1964 to 1986. Shaded regions represent dry years as discussed in text.

gyre-like nature of the sub estuary, location of broodstock has no effect on the timing of oyster settlement. The combination of low run-off and higher temperatures (compared with the other two systems) is implicated and is arguably an effect of directed climate change.

ABSTRACT The aim of the study is to reveal the gametogenic cycle in the pearl oyster, *Pteria penguin*. The specimens were collected from Si-chang Island (Thailand) from January 2000 to January 2001. Gametogenesis was observed in histological preparations of gonads from 142 adults sampled monthly. Spermatogenesis was classified into 10 stages: spermatogonia, 5 stages of primary spermatocyte, secondary spermatocyte, 2 stages of spermatid, and spermatozoa. Oogenesis was comprised of 6 stages: oogonia and 5 stages of oocyte. Three stages of gonad development were identified in the male: developing, mature, and partial spawning. In the female, there were 4 stages of gonad development: developing, mature, partial spawning, and spent. The spawning cycle of the male was observed throughout the year with a peak of partial spawning in March to June (60%) and in December to January (40%). Females spawned in June and July (50%). The water temperature and the salinity were not correlated to the reproductive cycle of *P. penguin*. The results of this study can be applied to the induction of spawning and the production of seed in the aquaculture system of this pearl oyster species.

KEY WORDS: *Pteria penguin*, gametogenic cycle, pearl oyster

INTRODUCTION

There are many species of pearl oyster in Thailand. Among these species only 3 species, *Pinctada maxima*, *Pinctada fucata*, and *Pteria penguin*, are widely cultivated in Phuket Island, Phuket Province, and Samed Island, Rayong Province. *P. maxima* produce large and good quality pearls. They are widely cultured to produce round pearls, which are quite expensive. *P. fucata* are smaller in size and they are cultured to produce small round pearls. *P. penguin* are medium in terms of size and are cultured to produce hemispherical pearls.

Pearl culture presents a significant potential for economic development in coastal village communities throughout the range of the more valuable species. The industry requires minimal capital input, yet has wide ranging benefits to farmers, coastal communities, and national economies. Pearls are the ideal export commodity; they are nonperishable, shipping costs are negligible, and lucrative markets are already established.

The biology of pearl oysters is poorly understood considering the importance of pearl culture and shell fisheries (Chellem 1987, Gervis & Sims 1992). Research and development priorities in developing countries include the assessment and protection of remaining stocks, evaluation of culture potential, and definition of management strategies for disease prevention. Improvements in spat collection methods, recent hatchery culture successes, selective breeding and genetic manipulation, and advances in pearl implantation techniques all have potential applications in village-based production (Alagarswami et al. 1987).

Among pearl cultures in Thailand, only that of *P. maxima* has been extensively studied, especially in regard to obtaining spat. They are the most important species in the pearling industry of Thailand. For the other two species, they are either collected from the sea or their spats are imported from Japan. There has been an attempt to culture *P. penguin* at Phuket Island but it is still at the early stage. In addition, information on the reproductive biology

such as gametogenesis and reproductive cycles of these three species of pearl oyster is still lacking in Thailand. Because *P. penguin* can be easily collected by SCUBA diving, this species was chosen to study gametogenesis and the reproductive cycle.

MATERIALS AND METHODS

Ten to 15 *P. penguin* pearl oysters were collected monthly between January 2000 and January 2001 from natural stock in the Si-chang Islands, Chonburi Province. Specimens were collected by SCUBA diving at 15–18 m depth. The pearl oysters were measured for shell length and shell width with Vernier calipers and the soft body weights were recorded. Water temperature and salinity at the collecting site were recorded.

A total of 142 *P. penguin* pearl oysters (72 males and 70 females) were examined histologically to determine the gametogenic cycle of both sexes. Gonad tissue between the proximal end of the gut loop and the base of the foot was excised to obtain the largest sections possible (Rose et al. 1990, Wada et al. 1995). Samples were fixed in Bouin's solution overnight. The tissues were then washed in 70% ethyl alcohol, dehydrated with a graded series of ethyl alcohol (70% to 100%) for 30 minute each, embedded in paraffin and sectioned and stained with Harris hematoxylin-eosin or PAS hematoxylin. Sections were observed and photographed under an Olympus CH40 light microscope.

In addition, samples of gonads were fixed in 3% glutaraldehyde in 0.1 M sodium cacodylate buffer (pH 7.8) for 24 hours. The tissues were then washed in the buffer solution and postfixed for 1 hour in 1% osmium tetroxide in 0.1 M buffer. After being dehydrated in a graded series of ethyl alcohol, the tissues were embedded in Araldite 502 resin. Sections (1 μ m) were stained with 1% methylene blue and observed under an Olympus CH40 light microscope.

RESULTS

The water temperature and salinity at the collecting site of pearl oyster, *P. penguin* were measured every month. The water tem-

*Corresponding author. E-mail: semkt@mahidol.ac.th

perature was not much different all year round being in the range of 26.8–30°C. The salinity at the collecting site was quite stable all year round (30–32 ppm).

In general, the female *P. penguin* shells were slightly larger than those of males. The mean shell width and length were 14.59 ± 1.69 cm and 11.32 ± 1.34 cm, respectively. Male and female *P. penguin* could not be distinguished by their shell morphology. Gonad color was also an unreliable indicator of sex. The gonads of *P. penguin* were not discrete organs, but were a greater proliferation of gonad follicles in the area between the byssal gland and gut loop. Gonad follicles proliferate within the connective tissue between the epithelium and the visceral mass.

Classification of Germ Cells

Germ cells appearing in the histologic sections of gonads of *P. penguin*, as observed by light microscope in paraffin and plastic-embedded semithin sections, could be classified as follows:

1. Spermatogenesis

The testis of *P. penguin* is composed of several acini, each surrounded by connective tissue. Based on nuclear characteristic and cell size, the male germ cells of *P. penguin* can be classified into 10 stages. They are spermatogonium, 5 stages of primary spermatocyte, secondary spermatocyte, 2 stages of spermatid and spermatozoa (Fig. 1).

Spermatogonium (Sg). The spermatogonia are attached largely to the acinus wall. The cell is spherical or oval shaped with nuclear size about 5 μ m in diameter (Fig. 1A). The nucleus contains mostly euchromatin and small blocks of heterochromatin dispersed throughout (Fig. 1A). The thin cytoplasm was stained light blue with methylene blue and the nucleolus is distinguishable within the nucleus.

Primary spermatocyte (PrSc). The primary spermatocyte consists of 5 stages: leptotene (LSc), zygotene (ZSc), pachytene (PSc), diplotene (DSc) and metaphase (MSc) (Figs. 1 A, B, C). The distinctive differences among various PrSc are the chromatin condensation pattern and the amount of euchromatin and heterochromatin.

Leptotene spermatocyte (LSc). The spherical-shaped cell of LSc is larger than Sg with a nuclear size approximately 5 μ m in diameter (Fig. 1B). The chromosome begins to condense into small blocks of heterochromatin and are scattered throughout the nucleus (Fig. 1B). The nucleolus is still present.

Zygotene spermatocyte (ZSc). The cell in this stage is approximately the same size as LSc (nuclear diameter of 5 μ m) (Fig. 1C). The heterochromatin blocks become larger and increase in thickness (Fig. 1C). The nucleolus is no longer distinct.

Pachytene spermatocyte (PSc). The PSc cell is smaller than ZSc (Figs. 1A, C). The nucleus contains mostly heterochromatin which are long thick fibers and are arranged in bouquet-like pattern (Figs. 1A, C). The nucleolus is not visible.

Diplotene spermatocyte (DSc). The nuclear size of DSc is about 4 μ m in diameter. The chromatin strands become increasingly condensed and are more visible than those of the earlier stages (Fig. 1A).

Figure 1. Semithin sections of the testis demonstrating various stages of male germ cells. (A–C) The spermatogonia (Sg) and different stages of primary spermatocyte (PrSc) are lying close to the follicular wall. LSc, leptotene spermatocyte; ZSc, zygotene spermatocyte; PSc, pachytene spermatocyte; DSc, diplotene spermatocyte; MSc, metaphase spermatocyte; SSc, secondary spermatocyte. (D) Spermatids I,2 ($St_{1,2}$).

Metaphase spermatocyte (MSc). The cell in this stage displays the condensed chromatin (Fig. 1A). The nuclear size is similar to those of the previous stages. The thick chromatin strands move to align along the center of the cell (Fig. 1A).

Secondary spermatocyte (SSc). SSc is a round cell. The thick chromatin blocks are clumped along the cell periphery (Fig. 1C).

Spermatid. Spermatid consists of spermatid I and II.

Spermatid I (St_1). The cell becomes smaller than SSc (Fig. 1D). Its nucleus is spherical and about 1.5–2 μ m in diameter and is located close to the lumen. The chromatin appears as small, thin clumps throughout the cell (Fig. 1D).

Spermatid II (St_2). The general features of St_2 are similar to those of St_1 but the cell size is decreased and the chromatin becomes completely condensed (Fig. 1D).

Spermatozoa (Sz). The cell is spherical with 1 μ m in diameter. The nucleus contains dense chromatin (Fig. 1D). The acrosome is not visible in semithin section. The heads of spermatozoa are separated from trabeculae and aligned in rows (Fig. 1D).

2. Oogenesis

The ovary of *P. penguin* is composed of several acini enclosed by trabeculae or connective tissue. Early-staged oocytes are attached to the trabeculae and mature oocytes are located in the lumens of acini (Fig. 2B). There are 6 stages of female germ cells of *P. penguin* based on cell size and shape. They are the oogonium and 5 stages of oocyte (Fig. 2).

Oogonium (Og). The oogonium is round in shape (Figs. 2A, B). The nuclear envelope is not distinct. Og is about 3.5 μm in size and contains mostly euchromatin (Fig. 2A). The cells are attached to the inner side of trabeculae (Fig. 2A).

Oocyte I (Oc₁). Oc₁ is about 14 μm in size. The nucleus is round and about 8 μm in diameter (Figs. 2A, B). It contains mostly euchromatin, which is dispersed throughout the nucleus. The nucleolus is clearly present (Figs. 2A, B). The Oc₁ cells are attached to the trabeculae (Fig. 2B).

Oocyte II (Oc₂). Oc₂ contains a large nucleus and a thin cytoplasm (Fig. 2B). The cell size is about 18 \times 22 μm , with the

Figure 2. Paraffin section of the ovary showing the oogenic unit, which consists of several acini (Ac). (A, B) Early stage oocyte, oogonium (Og), oocyte I (Oc₁), oocyte 2 (Oc₂), and oocyte 3 (Oc₃), are attached to the trabeculae (Tr). (C, D). The mature oocytes, oocyte 4 (Oc₄) and oocyte 5 (Oc₅), are located in the lumen of the acinus. The mature oocyte exhibits basophilic cytoplasm. Yolk granules (y) are dispersed throughout the cytoplasm and the thin jelly coat (arrow heads) is clearly present.

nuclear size about 11 \times 12 μm . The nucleus contains a distinct nucleolus (Fig. 2B). Lipid droplets are present in the cytoplasm. Oc₂ are still attached to the trabeculae (Fig. 2B).

Oocyte III (Oc₃). The cell size is about 25 \times 31 μm , with the nuclear size being about 15 \times 17 μm . The cell is larger in size and the nucleus contains mostly euchromatin (Figs. 2B, D). There are numerous yolk granules, which are dispersed throughout the cytoplasm. Oc₃ cells still remain attached to the trabeculae at the base of the cell (Figs. 2B, D).

Oocyte IV (Oc₄). The cell is large and it assumes the droplet shape (Figs. 2C, D). The cell size is about 31 \times 51 μm , with the nuclear size being about 22 \times 26 μm . The nucleolus is clearly visible and the nucleus occupies most of the cell area (Fig. 2C). The ratio of cytoplasm to nucleus is about 0.44. Yolk granules are numerous. The Oc₄ cell is covered with a very thin jelly coat on the outer cell membrane (Figs. 2C, D). The cells are still attached to the trabeculae (Fig. 2D).

Oocyte V (Oc₅). This is the mature oocyte before spawning. Oc₅ is the largest cell and has a polygonal or round shape (Fig. 2D). The cell size is about 42 μm in diameter and the nuclear size is about 27 μm in diameter. The nucleus is very large when compared with that of Oc₄. The ratio of cytoplasm to nucleus is 0.56. Yolk granules are abundant. All Oc₅ cells are completely detached from the trabeculae but remain in the capsule (Fig. 2D).

Reproductive Cycle

The reproductive cycle of *P. penguin* was studied by observing the changes in the gonad histology. The stages of gonad maturation could be classified into 3 stages in the male (developing, mature, partial spawning) and 4 stages in the female (developing, mature, partial spawning, spent).

1. Male

Developing stage. The gonad was characterized by the expansion of the follicle and the appearance of spermatogonia along the follicular wall (Fig. 3A). Primary spermatocytes proliferate rapidly and move to the center of the follicular lumen (Fig. 3B). The spermatids and spermatozoa are present in the lumen but they are not abundant (Fig. 3B). The developing stage of the male occurred all year round but production of spermatocytes was highest in August and November (Fig. 5).

Mature stage. The gonad still contains early staged cells but they are attached to the wall like a narrow band. The spermatid and spermatozoa, which occupy most areas of the follicle, are radiating toward the center of the follicle. They arrange themselves in radial rows (Fig. 3C). The mature stage of male *P. penguin* occurred from February to March during the annual spermatogenic cycle (Fig. 5).

Partial spawning stage. This is the stage when the pearl oysters release mature gametes into the water. The gonad contains a few spermatozoa in the lumen and the follicular wall is wrinkled and partially collapsed (Fig. 3D). Partial spawning stage occurred twice a year, in January and April (Fig. 5).

2. Female

Developing stage. The ovary consisted of capsule-like structures, which mostly contained early stage oocytes, Og, Oc₁, Oc₂,

Figure 3. Paraffin sections of the testis showing various stages in the reproductive cycle. (A, B) the developing stage showing follicles that contain spermatogonia (Sg), primary spermatocyte (PrSc), spermatids (St), and spermatozoa (Sz). Spermatogonia are attached to the follicular wall and primary spermatocytes are located next to the spermatogonia on the inner side of the acini. (C) The mature stage contains mostly late spermatids and numerous spermatozoa, which lie in rows. The tails of spermatozoa are present in the center of the follicular lumen (arrow head). (D) Partial spawning stage showing partly empty follicles. The testis contains a few spermatozoa (Sz), spermatids (St) and primary spermatocytes (PrSc).

and Oc_3 (Fig. 4A). These oocytes were attached to the trabeculae (Fig. 4B). The developing stage occurred from August to December (Fig. 6).

Mature stage. In the mature ovary, there are abundant Oc_4 and Oc_5 , but only a few remaining early staged oocytes. Most oocytes have a polygonal or a drop shape, and display both nucleolus and nucleus (Fig. 4B). Some are attached to the trabeculae but most oocytes are free in the center of the acinus (Fig. 4B). The mature stage of the female occurred in January, August to September, and December (Fig. 6).

Partial spawning stage. The follicles of the ovary appear partially empty, indicating that some mature oocytes have been released (Fig. 4C). The follicles contain mostly Oc_4 and Oc_5 that have become rounded, polygonal, or pear shaped (Fig. 4C). The early-stage oocytes are still attached to the trabeculae (Fig. 4C). Partial spawning occurred in March and July (Fig. 6).

Spent stage. Mature oocytes are completely discharged and the follicles are almost empty (Fig. 4D). The follicular wall be-

comes wrinkled or degenerates and the gonads are greatly decreased in size (Fig. 4D). The spent stage of female *P. penguin* occurred in November and December (Fig. 6).

DISCUSSION

The characteristics of gametogenesis and stages of gonad development in *P. penguin* are similar to those described for the pearl oysters *P. albina* (Tranter 1958a), *P. margaritifera* (Tranter 1958c), *P. mazatlanica* (García-Domínguez et al. 1996), *P. fucata* (Tranter 1959, Wada et al. 1995), and *P. maxima* (Rose et al. 1990). However, previous authors did not emphasize the classification of germ cells. In *P. maxima* and *P. fucata fucata*, spermatogenic cells were classified into 4 stages: spermatogonia, spermatocyte, spermatid, and spermatozoa (Rose et al. 1990, Wada et al. 1995). In *P. albina*, Tranter (1958b) categorized male germ cells into 5 stages. Thielley et al. (1993) studied the ultrastructure of spermatogenic cells in *P. margaritifera* and classified them into 10 stages. Based on cell size and nuclear characteristics, the present study revealed 10 stages of spermatogenic cells: spermatogonia, 5 stages of primary spermatocyte, secondary spermatocyte, 2 stages

Figure 4. Paraffin sections of the ovary showing the female reproductive cycle. (A) The developing stage mainly contains early stage oocytes, oogonia (Og) and oocytes stage 1–3 (Oc_{1-3}) in the acini (Ac). (B) The mature stage mostly contains a few early stage oocytes (Oc_3), and late stage oocytes (Oc_{4-5}) that have increased in size and number. (C) Partial spawning stage showing partly emptied follicles. The ovary contains a few early stage oocytes and the mature oocytes (Oc_4 , Oc_5) are free in the follicular lumen. (D) The spent stage showing the empty follicles after the discharge of mature oocytes. There are still some oogonia (Og) and oocytes (Og, Oc_{1-4}) in the follicle.

Figure 5. The annual spermatogenic cycle of *P. penguin* from monthly collections between January 2000 and January 2001.

of spermatid, and spermatozoa. However, in this study the acrosome could not be seen on the anterior end at high magnifications, which was different from that reported for *P. albina* (Tranter 1958b) and the primary and secondary spermatogonia could not be distinguished like those found in *P. margaritifera* (Thielley et al. 1993). In addition, diakinetid primary spermatocytes were not observed; only metaphase primary spermatocytes were found. This study identified 2 stages of spermatid based on nuclear size and chromatin condensation, but in *P. margaritifera*, only one stage of spermatid was found.

The spermatogonium is the cell whose nucleus contains a single nucleolus and small clumps of dense chromatin. The spermatogonium divides into the first meiotic division to give rise to the primary spermatocyte. Prophase cells exhibit a different form of chromatin condensation. The chromatin appears as a very dense cluster in the leptotene spermatocyte. The zygotene spermatocyte is characterized by the presence of a synaptonemal complex in *P. margaritifera* (Thielley et al. 1993). However, a synaptonemal complex could not be identified in the zygotene spermatocyte of *P. penguin* in this study. In the secondary spermatocyte, the thick

chromatids are clumped along the cell periphery. Spermatids are classified into spermatid I and spermatid II, whose chromatins become condensed throughout spermatogenesis. During the process, the few clear areas between chromatin masses are reduced in size (Thielley et al. 1993). Baccetti and Afzelius (1976) described 4 main types of sperm: primitive, modified, biflagellate, and aflagellate. Most studies have shown that bivalves have "primitive spermatozoa" (Dohmen 1983). The spermatozoa of *P. penguin* is of the primitive type, similar to those of other bivalves. Primitive sperms are typical of animals that spawn their gametes into surrounding water.

Literature on oogenesis of pearl oysters in the Family Pteriidae is very scarce, especially on *Pteria* species. Various stages of oogenesis have been described along with reproductive cycles in *P. maxima* and *P. fucata fucata* (Rose et al. 1990, Wada et al. 1995). *P. maxima* has 4 stages of oogenesis (Rose et al. 1990), whereas 3 stages were identified in *P. fucata fucata* (Wada et al. 1995). According to Tranter (1958b), oogenesis of *P. albina* occurred in 6 stages. This study identified 6 stages of oogenesis in *P. penguin* (oogonia, 5 stages of oocytes Oc₁₋₅) based on cell size, nuclear size, basophilic cytoplasm, presence of yolk granules, and jelly coat. These oogonia are in the previtellogenic phase, which is characterized by the growth of oocytes and an increase in volume of the nucleus and cytoplasm (Dohmen 1983).

Oc₃₋₅ in *P. penguin* could be classified into the vitellogenic phase. During this period the oocytes grow rapidly, mainly because of the accumulation of yolk and other nutrient substances such as glycogen and lipid (Dohmen 1983). The cytoplasm increased in size due to the presence of yolk granules. This study did not identify glycogen or lipid droplets, but the yolk granules were quite distinct.

Similar to *P. albina* (Tranter 1958b), Oc₄ are larger in size and the cytoplasm stains more heavily as yolk accumulates. Besides the presence of yolk granules, both Oc₄ and Oc₅ are surrounded by a thin jelly coat, which stained positively with PAS, indicating that it is mucopolysaccharide in nature. Oc₅ could be distinguished from Oc₄ by the larger nucleus and detachment from the trabeculae (Tranter 1958b).

Histological examinations of the ovarian and testicular tissues of *P. penguin* showed a definite annual reproductive cycle. Previ-

ous studies simplified the gametogenic cycle of family Pteriidae into 5 to 7 stages, which are clearly defined in females (Rose et al. 1990, Wada et al. 1995, Pouvreau et al. 2000). In this study, histological examination determined 3 stages in the male and 4 stages in the female. In the male, they are the developing, mature, and partial spawning stages. Spent or completely empty follicles of the testis were not observed in the male *P. penguin*. In the female, gonad development stages are developing, mature, partial spawning, and spent stages. In general, the gametogenic cycle is clearly defined in female *P. penguin*. The present study could only identify the main stages as described previously.
